Comparison of the Crystal Structures of the Human Manganese Superoxide Dismutase and the Homologous Aspergillus fumigatus Allergen at 2-Å Resolution

Sabine Flückiger,* Peer R. E. Mittl,† Leonardo Scapozza,‡ Helmi Fijten,* Gerd Folkers,‡ Markus G. Grütter,† Kurt Blaser,* and Reto Crameri†∗

Manganese superoxide dismutase (MnSOD) of Aspergillus fumigatus, a fungus involved in many pulmonary complications, has been identified as IgE-binding protein. It has been shown also that MnSODs from other organisms, including human, are recognized by IgE Abs from individuals sensitized to A. fumigatus MnSOD. Comparison of the fungal and the human crystal structure should allow the identification of structural similarities responsible for IgE-mediated cross-reactivity. The three-dimensional structure of A. fumigatus MnSOD has been determined at 2-Å resolution by x-ray diffraction analysis. Crystals belonged to space group P2₁2₁2₁, with unit cell dimensions of a = 65.88 Å, b = 98.7 Å, and c = 139.28 Å. The structure was solved by molecular replacement using the structure of the human MnSOD as a search model. The final refined model included four chains of 199–200 amino acids, four manganese ions, and 745 water molecules, with a crystallographic R-factor of 19.4% and a free R-factor of 23.3%. Like MnSODs of other eukaryotic organisms, A. fumigatus MnSOD forms a homotetramer with the manganese ions coordinated by three histidines, one aspartic acid, and one water molecule. The fungal and the human MnSOD share high similarity on the level of both primary and tertiary structure. We identified conserved amino acids that are solvent exposed in the fungal and the human crystal structure and are therefore potentially involved in IgE-mediated cross-reactivity. The Journal of Immunology, 2002, 168: 1267–1272.

S

uperoxide dismutases (SOD; EC 1.15.1.1) are metalloenzymes that catalyze the dismutation of toxic superoxide radicals to oxygen and hydrogen peroxide and are considered as the first line of defense against the toxicity of oxygen-related radicals (1). The SODs can be subdivided into three classes, depending on the metal cofactor used: iron SOD and manganese SOD (MnSOD), which are homologous in sequence and share a similar αβ fold (2), and the structurally unrelated Cu, ZnSOD with a Greek key β-barrel fold (3). While Cu, ZnSOD occurs primarily in eukaryotes and iron SOD in prokaryotes, MnSOD is found in both prokaryotes and mitochondria (1). Prokaryotic and eukaryotic MnSODs differ in their usually dimeric and tetrameric structure, respectively (4). Exceptions are the tetrameric MnSODs from the extreme thermophiles Thermus thermophilus and Thermus aquaticus (5, 6). The crystal structures have been solved for the MnSODs of Bacillus stearothermophilus (7), Thermus thermophilus (8), Homo sapiens (4, 9), Propionibacterium shermanii (10), and Escherichia coli (11). In all MnSOD structures known, the active center is exceptionally highly conserved and three histidines and one aspartic acid residue have been identified as metal ligands (10). The MnSOD of Aspergillus fumigatus, a fungus involved in many pulmonary complications ranging from benign colonization of the lung to life-threatening diseases (12), has been isolated as an IgE-binding protein from a cDNA library displayed on the surface of filamentous phage (13). Furthermore, it has been shown that the homologous proteins from Saccharomyces cerevisiae, Drosophila melanogaster, and E. coli are able to bind IgE from individuals sensitized to A. fumigatus MnSOD (14). These data suggest that MnSODs from phylogenetically distant species represent a family of cross-reactive structures involved in allergic reactions. The most surprising observation was that both A. fumigatus and human MnSOD were recognized by IgE Abs from subjects allergic to A. fumigatus MnSOD and elicited specific immediate type skin reactions in these individuals (15). Moreover, both human and A. fumigatus MnSOD induced proliferation in PBMC of A. fumigatus-allergic subjects who showed specific IgE responses and reacted in skin tests to MnSOD (15). These data provide strong evidence for in vitro and in vivo humoral and cell-mediated autoreactivity to human MnSOD in patients allergic to A. fumigatus. IgE-mediated autoimmunity to self Ags is an emerging phenomenon that may contribute to exacerbation and/or perpetuation of severe atopic diseases in the absence of exogenous allergen exposure (16, 17). To elucidate whether the mechanisms of these IgE-mediated autoimmune reactions are based on molecular mimicry between conserved B cell epitopes present on allergens and on the structurally related human counterparts, exact comparisons of the three-dimensional structure of the proteins are required. Furthermore, to identify the solvent-exposed amino acids accessible for Ag/Ab interactions on the surface of an allergen, its crystal structure is needed. In this study we...
present the crystal structure of *A. fumigatus* MnSOD at 2-Å resolution. The structure of the human MnSOD has been determined at 2.2-Å resolution and deposited in the Brookhaven Protein Data Bank (PDB) with the ID 1ABM (4). We combined data on conserved amino acid residues in the two homologous sequences with data on the solvent accessibility of the residues in the two crystal structures and identified the amino acids potentially involved in IgE-mediated cross-reactivity as a first step to engineer MnSOD molecules devoid of cross-reactive B cell epitopes.

Materials and Methods

**Cloning, expression, and purification of *A. fumigatus* MnSOD**

*A. fumigatus* MnSOD was originally isolated from a cDNA library displayed on the surface of filamentous phage using IgE of individuals sensitized to the fungus as ligand (15). The sequence encoding the mature fungal enzyme was cloned as BglIII/HindIII fragment into BamIII/HindIII-restricted high level expression vector pQE16 (Qiagen, Hilden, Germany), thereby eliminating the [His]6, fusion tag, and transformed into competent *E. coli* strain M15 by electroporation (18). Single transformants were picked and grown at 30°C in 2YT medium to an OD600 of 0.7, induced by 2 mM isopropyl-β-D-thiogalactoside and harvested after another 4 h of incubation by centrifugation at 6,000 × g for 10 min at 4°C. Pellets were stored at −80°C until use. Precipitated cell pellets from 1 liter of culture were thawed by transfer to an ice/water bath for 20 min and subsequently frozen for 20 min at −80°C. This cycle was repeated three times to release recombinant protein (19). Thereafter, cell pellets were resuspended in 10 ml of 50 mM PIPES, pH 7.0, and placed in an ice/water bath for 60 min. Samples were then centrifuged at 10,000 × g (15 min at 4°C) and the supernatants containing the recombinant protein were separated from the pellets. Recombinant MnSOD was stepwise precipitated using ammonium sulfate and precipitates were resuspended in TBS buffer (pH 7.4) and analyzed by SDS-PAGE (4–20%; NOVEX, San Diego, CA) under denaturing, reducing conditions. For further purification the fractions containing recombinant MnSOD were loaded onto a Fractogel EMD triethylaminoethyl Sepharose (M) column (Merck, Darmstadt, Germany) and eluted with a linear NaCl gradient at pH 8. Thirty to 40 mg of pure MnSOD were typically isolated from 1 liter of culture. The protein was reconstituted by dialysis against water containing 0.1 mM MnCl₂. Molecular size and purity were analyzed by denaturing, reducing SDS-PAGE and native-like folding was confirmed by determination of the enzymatic activity (14). For crystallization experiments the recombinant protein was concentrated to 15 mg/ml by ultrafiltration (Centrex UF-2; Schleicher & Schuell, Dassel, Germany).

**Crystallography and data collection**

*A. fumigatus* MnSOD was crystallized by the hanging-drop vapor-diffusion method. Among the crystallization conditions screened, the best results were achieved with polyethylene glycol 400 as precipitant. The solution of a crystallization drop was prepared by mixing 2 µl of protein solution (15 mg/ml in water, 0.1 mM MnCl₂) with 2 µl of reservoir solution (27% polyethylene glycol 400, 100 mM Tris-HCl, pH 8). The droplets were equilibrated against 500 µl of reservoir solution at 23°C. Rhombohedral crystals grew within a few days.

X-ray diffraction analysis was performed using CuKα radiation generated by a Nonius FR 591 rotating anode generator (Nonius, Delft, The Netherlands) equipped with a double-focusing mirror system (XRM-216; Prophysics, Zürich, Switzerland). Data were recorded on an imaging plate detector (300 mm; Mar Research, Norderstedt, Germany) with a detector to crystal distance of 120 cm. Crystals were flash-frozen in a stream of cold nitrogen gas after soaking in cryoprotectant solution (22% v/v) glycerol in reservoir buffer) and measurements were performed at 100 K. Under these conditions crystals were stable and diffracted x-rays to 2-Å resolution. A data set was collected for one crystal (85 × 85 × 850 µm) and processed with the DENZO and SCALEPACK crystallographic data reduction package (20). The crystal belonged to space group *P2₁2₁2₁* with the unit cell parameters *a* = 65.88 Å, *b* = 98.7 Å, and *c* = 139.28 Å. Assuming four molecules of 22 kDa in the asymmetric unit, the calculated Matthews coefficient *Vₐ* = 2.57 Å³/Da, corresponding to a solvent content of 52.5% (21). Statistics on data collection are given in Table I.

**Molecular replacement**

The structure of *A. fumigatus* MnSOD was solved by molecular replacement using the program AMORE (22). The structure of the human MnSOD dimer (PDB ID 1ABM (4), which shares 45% sequence identity with *A. fumigatus* MnSOD, was used as a search model. The cross-rotation function calculated with data between 8- and 3.4-Å resolution yielded two peaks of similar heights (8.7 and 8.55 σ, respectively) that were substantially higher than the third-highest peak (3.5 σ). The first translation function was calculated for the search model that was rotated according to the Eulerian angles of the highest peak of the cross-rotation function using data between 8- and 3.3-Å resolution. A significant 9-σ peak was observed for the correctly positioned search model. To find the shift for the second dimer, the search model was rotated according to the Euler angles of the second-highest peak in the cross-rotation function while the parameters for the first dimer were held constant. A 22-σ peak was observed for the correct translation of the second search model. Two copies of the dimeric MnSOD model were transformed by α = 90.58°, β = 37.25°, γ = 21.56°, *a* = 0.1953, *b* = 0.4101, *c* = 0.0802 and *α* = 86.93°, *β* = 36.75°, *γ* = 18.34°, *a* = 0.6880, *b* = 0.9146, *c* = 0.7541, respectively, to yield the correctly positioned tetramer. After 10 cycles of rigid-body refinement (8- to 3-Å resolution) the R-factor was 45.3%.

**Refinement**

The refinement of the *A. fumigatus* MnSOD model was performed with the crystallographic and NMR system program (23). In the initial stages the simulated annealing protocol was used followed by several cycles with the refine protocol that combined simulated annealing with energy minimizing and B factor refinement. Manual corrections of the model were performed by examination of the (2Fo − Fc) and (Fo − Fc) maps with program O (24). The manganese atoms were placed in the active sites and a total of 745 solvent molecules were added using the water pick protocol implemented in the crystallography and NMR system. Noncrystallographic symmetry restraints were gradually omitted and data were extended to 2-Å resolution. After several cycles of manual fitting, refinement and addition of water molecules the final R-factor was 19.4% and the free R-factor was 23.3%. The statistics of the final model are summarized in Table I. The stereochemistry of the *A. fumigatus* MnSOD model was checked with PROCHECK (25). The Swiss-Pdb Viewer (26) was used for figure production.

**Calculation of the solvent-accessible area**

The solvent-accessible surface area of the final model was calculated with the program Access (S. J. Hubbard and J. M. Thornton, Department of Biochemistry and Molecular Biology, University College, London, U.K.) using a probe radius of 1.4 Å (27). The relative residue-accessible area is the ratio of the accessible area of an amino acid in the model to the accessible area of the amino acid in a tripeptide.

**Accession number**

Structural data is accessible from the PDB (ID code 1KKC).
Results

The overall structure of \textit{A. fumigatus} MnSOD

The crystal structure of \textit{A. fumigatus} MnSOD was solved at 2-Å resolution by molecular replacement and refined to a crystallographic \( R \)-factor of 19.4\% (free \( R \)-factor 23.3\%). The final parameters of refinement are given in Table I. The final model of \textit{A. fumigatus} MnSOD consists of four chains with 199 or 200 amino acid residues (chain A: Gln\(^{14}\) to Lys\(^{213}\); chain B: Gln\(^{15}\) to Lys\(^{213}\); chain X: Gln\(^{15}\) to Gly\(^{214}\); chain Y: Gln\(^{14}\) to Lys\(^{213}\)), four manganese atoms, and 745 water molecules. A total of 99.6\% of the non-glycine and non-proline residues have main chain dihedral angles within the allowed regions of the Ramachandran plot (28) as determined by PROCHECK. For the three residues (Asp\(^{160}\) of chains A, X, and Y) that fell in the disallowed region clear electron density was visible. One cis proline per monomer (Pro\(^{30}\)) in analogy to human MnSOD has been detected.

\textit{A. fumigatus} MnSOD forms a homotetramer in the crystal (Fig. 1. \textit{A} and \textit{B}) which is in agreement with structures of MnSODs from other eukaryotic organisms. The structures of each of the four chains in the crystallographic asymmetric unit are very similar. Superposition of the backbones of chains A and B and X and Y, respectively, results in root-mean-square (rms) deviations of 0.23 and 0.29 Å, respectively (0.51 Å for all atoms in both cases). The dimer formed by chains A and B and the dimer formed by chains X and Y can be superimposed with a rms deviation of 0.27 Å for the main chain atoms and 0.61 Å for all atoms. The two dimers pack tightly together to form the tetramer that has a 222 non-crystallographic symmetry. The overall fold of one monomer and the active site geometry are shown in Fig. 1, \textit{C} and \textit{D}. Each chain contains seven \( \alpha \)-helices and five strands of \( \beta \)-sheet (Fig. 1\textit{C}). In the active site of each subunit manganese is bound by three histidines, His\(^{40}\), His\(^{88}\), and His\(^{178}\), one aspartic acid, Asp\(^{174}\), and one water molecule (Fig. 1\textit{D}). This is in accordance with the metal coordination residues found in all known MnSOD structures (10).

The four subunits are indicated by different colors: A, yellow; B, blue; X, red; Y, green. Manganese ions are shown as orange spheres. C and D, Subunit fold and active site geometry of \textit{A. fumigatus} MnSOD. C, The overall structure of one monomer is shown in ribbon representation: \( \alpha \)-helices, red; \( \beta \)-sheets, green; turns, yellow. Each subunit contains seven \( \alpha \)-helices (\( \alpha_1\)–\( \alpha_7 \)) and five \( \beta \)-sheets (\( \beta_1\)–\( \beta_5 \)). The manganese ion is shown as orange sphere. The protein ligands coordinating the manganese ion are drawn in a white stick representation. The water molecule occupying the fifth coordination site is shown as light blue sphere (enlarged for better clarity). D, Close-up view of the active site of one subunit of \textit{A. fumigatus} MnSOD. The amino acid residues surrounding the active site are drawn in a stick representation. The manganese ion (orange sphere) is bound by His\(^{40}\), His\(^{88}\), Asp\(^{174}\), and His\(^{178}\). The fifth coordination site is occupied by a water molecule (light blue sphere). The (2\(F_o\) – \(F_c\)) electron density map contoured at 1 \( \sigma \) is of good quality.}
\end{figure}
MnSODs belong to a family of highly conserved proteins. On the sequence level, \textit{A. fumigatus} MnSOD shares 45\% identity and 65\% similarity with the human MnSOD. Both enzymes are tetrameric with high similarity in the overall structure. Superposition of the backbones of the two tetramers gives an rms deviation of 1.48 Å (Fig. 2A) while the monomers can be superimposed with a rms deviation in the range of 0.9 Å. Obvious differences in the two structures are detected only in some loop regions. These include the two regions from residues 99 to 101 and 104 to 108 with insertions, the turn between residues 148 and 151, and the region within residue 160 and 170 with deletions in the fungal sequence compared with the human MnSOD sequence (Fig. 3). The program Naccess was used to calculate the solvent-accessible surface area of the two structures and the relative residue-accessible area, using a probe radius of 1.4 Å. Only those residues that are at least partly exposed to solvent can contribute to IgE binding. Therefore, the amino acids that are identical or similar in the fungal and human sequence and solvent exposed in both structures are potentially involved in the IgE-mediated cross-reactivity between the two proteins. Fig. 3 shows a sequence alignment of chain A of \textit{A. fumigatus} and human MnSOD. A total of 101 of the 224 residues in the alignment are identical, and 145 are identical or similar. Of the 101 identical amino acids, 17 are at least 30\% and 10 thereof are at least 50\% solvent exposed in both structures. These amino acids are considered to be the most likely candidates involved in Ab-mediated (IgE) cross-reactivity of the two proteins. If the similar residues are taken into account, a total of 34 and 20 are at least 30 and 50\% solvent exposed, respectively. These putative IgE-binding residues that could be involved in several B cell epitopes elicited by a polyclonal immune response are scattered over the whole sequence (Fig. 3), in agreement with the findings that B cell epitopes elicited by natural exposure are discontinuous (29).

The contribution of amino acid residues to the binding of specific serum IgE to an allergen can be determined by site-directed mutagenesis and testing of the IgE-binding capacity of the mutants. To narrow down the initial number of residues to be subjected to further investigations, the sequences of other MnSODs have been included to identify conserved residues. It has been shown also that the MnSODs from \textit{S. cerevisiae}, \textit{D. melanogaster},...
FIGURE 4. The molecular surface of subunit A of A. fumigatus MnSOD, determined with a probe radius of 1.4 Å, showing putative IgE-binding amino acid residues. Amino acids that are identical in the sequences of A. fumigatus, human, S. cerevisiae, D. melanogaster, and E. coli MnSOD and at least 30% solvent exposed in the crystal structure of the A. fumigatus and the human MnSOD tetramer are shown in red and labeled. Pro30 and Asn50 are >50% solvent exposed. Of the amino acids that are similar in the five sequences, 11 are at least 30% solvent exposed in the fungal and human structure (shown in green).

and E. coli are able to bind IgE from A. fumigatus-sensitized individuals (14), suggesting IgE cross-reactivity between these organisms. Sequence alignment of the MnSODs from these organisms together with the MnSODs from A. fumigatus and human results in an identity of 19% and a similarity of 34% of the alignment length (48 identical plus 38 similar amino acids). Of the identical residues only four (Pro19, Pro30, Lys43, and Asn50) are at least 30% and only two (Pro30 and Asn50) are at least 50% solvent exposed in the fungal and the human crystal structure (Fig. 4). Therefore, Asn50 and Lys43 could be the first suitable targets for substitution by site-directed mutagenesis. If the similar amino acids shared between the MnSODs studied are included, five additional residues (Gln39, Glu38, Thr37, Glu37, and Asn197) are 30–50% and six (Thr37, Gln35, Lys61, Asp123, Lys124, and Lys193) are at least 50% solvent exposed. The latter could form the second group of candidates for mutational studies.

Discussion

The number of known allergen structures, elucidated either by x-ray crystallography or homology modeling, is increasing. However, so far no characteristic structural or functional features of allergens have been detected that would allow the prediction of the allergenicity of a protein. It seems that in principle any protein has the potential to act as an allergen (30). In contrast to allergenicity, which is an intrinsic property of many different molecular structures, Ab-mediated cross-reactivity among homologous proteins is largely determined by common structural features shared between protein families (29). The only reliable method to determine the complete structure of a B cell epitope is to cocrystallize the Ag with a mAb Fab and determine the structure of the complex by x-ray crystallography. The atomic details of interaction are known for more than 30 Ag-Ab combinations (30). Recently, the first structure of an allergen-Fab complex, the major birch pollen allergen Bet v 1 complexed with the Fab of a murine monoclonal IgG1 Ab, has been elucidated (31). Because crystallization and x-ray crystallography require homogeneous reagents, polyclonal human serum IgE cannot be used. Furthermore, monoclonal human IgE is difficult to obtain. Therefore, mAbs from other sources must be generated for crystallization of Ag/Ab complexes. An alternative approach to identify IgE-binding epitopes is to determine shared features of cross-reactive allergens on the level of primary and tertiary structure. We used this approach to identify amino acid residues potentially involved in IgE-mediated cross-reactivity between MnSODs of different origin. Notably, humoral and cell-mediated autoreactivity to human MnSOD in patients allergic to A. fumigatus has been clearly shown (15). The crystal structure of A. fumigatus MnSOD was determined at 2-Å resolution and comparison with the structure of the human MnSOD, which had been determined at 2.2-Å resolution (4), revealed a high similarity between the two structures. Although the fungal and the human sequence share 101 identical amino acids, only 17 thereof are >30% and only 10 are >50% solvent exposed in both structures and therefore likely to be accessible for Ag-Ab interactions (Fig. 2B).

Thus a large portion of the conserved amino acid residues is located in the core of the protein and inaccessible for Ag/Ab interactions, including the highly conserved residues defining the active center of the enzyme (Fig. 1D). Because Ab-mediated cross-reactivity between two proteins is dependent on shared structural features on the surface, at least some of the conserved, solvent-exposed amino acids identified in this study must be involved in the binding of polyclonal IgE. These residues are distributed over the whole sequence (Fig. 3), in agreement with the discontinuous structure found in B cell epitopes (29). In contrast, they are clustered over the whole surface (Fig. 2B), indicating that the entire surface of the MnSOD is potentially antigenic, as postulated by Laver et al. (29). The known B cell epitopes, which occupy a buried surface in the range of 540–890 Å2 (32), are formed by 15–22 amino acid residues on different surface loops, and their allergenicity is absolutely dependent upon conformation of the native proteins (29). Therefore, correct protein folding is essential for B cell epitope mapping. In the case of recombinant MnSOD, a native-like conformation could be confirmed by measurement of the enzymatic activity of the protein. Moreover, inhibition experiments using different MnSODs and serum of individuals sensitized to A. fumigatus MnSOD showed that the enzymes share common IgE-binding epitopes (14). Sequential site-directed mutagenesis of the conserved, surface-displayed amino acid residues described above will allow experimental determination of the contribution of each single residue to the clinically observed cross-reactivity of A. fumigatus-allergic individuals toward MnSODs from different species.

Acknowledgments

We thank Dr. Andrea Prota for his assistance in crystallization.
