Aberrant V(D)J Recombination in Ataxia Telangiectasia Mutated-Deficient Lymphocytes Is Dependent on Nonhomologous DNA End Joining

Andrea L. Bredemeyer,* Ching-Yu Huang,* Laura M. Walker,* Craig H. Bassing,†‡ and Barry P. Sleckman2*

During lymphocyte Ag receptor gene assembly, DNA cleavage by the Rag proteins generates pairs of coding and signal ends that are normally joined into coding joints and signal joints, respectively, by the classical nonhomologous end-joining (NHEJ) pathway of DNA double strand break repair. Coding and signal ends can also be aberrantly joined to each other, generating hybrid joints, through NHEJ or through NHEJ-independent pathways, such as Rag-mediated transposition. Hybrid joints do not participate in the formation of functional Ag receptor genes and can alter the configuration of Ag receptor loci in ways that limit subsequent productive rearrangements. The formation of these nonfunctional hybrid joints occurs rarely in wild type lymphocytes, demonstrating that mechanisms exist to limit both the NHEJ-dependent and the NHEJ-independent joining of a signal end to a coding end. In contrast to wild-type cells, hybrid joint formation occurs at high levels in ataxia telangiectasia mutated (Atm)-deficient lymphocytes, suggesting that Atm functions to limit the formation of these aberrant joints. In this study, we show that hybrid joint formation in Atm-deficient cells requires the NHEJ proteins Artemis, DNA-PKcs, and Ku70, demonstrating that Atm functions primarily by modulating the NHEJ-dependent, and not the NHEJ-independent, joining of coding ends to signal ends. The Journal of Immunology, 2008, 181: 2620–2625.
previously shown that, in Atm-deficient lymphocytes undergoing V(D)J recombination, there is an accumulation of unrepaired coding ends that are frequently resolved aberrantly as chromosomal translocations or large chromosomal deletions or inversions (22). In addition, there is a marked increase in hybrid joint formation during inversive rearrangements (22). We have proposed that the accumulation of unrepaired coding ends and the increase in hybrid joint formation could both be explained by a requirement for Atm to stabilize DNA DSB complexes generated after Rag-mediated DNA cleavage (22). These defects, however, could also reflect distinct requirements for Atm in promoting the NHEJ-dependent joining of coding ends and in prohibiting hybrid joint formation by NHEJ-independent pathways, such as Rag-mediated transposition. To distinguish between these possibilities, in this study, we determine whether hybrid joints generated in Atm-deficient cells form through NHEJ-dependent or NHEJ-independent joining pathways.

Materials and Methods

Mice

All mice were bred and maintained under specific pathogen-free conditions at the Washington University School of Medicine and were handled in accordance to the guidelines set forth by the Division of Comparative Medicine of Washington University.

Cell lines and culture conditions

Artemis−/−, Artemis−/−:Atm−/−, and Ku70−/− v-abl-transformed pre-B cells were generated by culturing bone marrow of 3- to 5-wk-old mice with the pMSCV v-abl retrovirus, as described previously (22). Cells were generated from at least two mice of each genotype, which all expressed an Eμ-Bcl-2 transgene. These cells (10⁶/ml) were transduced with the pMX-INV retrovirus by centrifugation at 1800 rpm for 90 min. Cells containing pMX-INV were isolated by fluorescence activated cell sorting based on expression of the human CD4 (hCD4). hCD4 expression was detected using PE-conjugated anti-hCD4 (BD Pharmingen). The wild type, Artemis−/− and scid abl pre-B cell lines containing pMX-INV have been described previously (22). Cells were treated with 3 μM STI571 (Novartis) for the indicated times at 10⁶ cells/ml. Ku-55933 (Sigma-Aldrich) was used at 15 μM.

Southern blot and PCR analyses

Genomic DNA was isolated and Southern blot analyses were conducted using the indicated restriction enzymes and the C4 probe as previously described (22). PCR analyses for hybrid joint formation during pMX-INV rearrangement in abl pre-B cells, and during Vβ14 and Vδ5 rearrangement in thymocytes, were performed as previously described (22). IL2 gene PCR was conducted as a DNA loading control as previously described (22).

Results

Increased hybrid joint formation in Atm-deficient abl pre-B cells

We have recently established an experimental approach whereby chromosomal V(D)J recombination can be analyzed in murine v-abl transformed pre-B cells, hereafter referred to as abl pre-B cells (22). Rag gene expression and G1 cell cycle arrest can be induced in these cells upon inhibition of v-abl kinase activity with STI571 (22, 25). This leads to robust rearrangement of the endogenous IgL locus and introduced retroviral recombination substrates, such as pMX-INV (Fig. 1). pMX-INV has a pair of RSs that are oriented such that normal rearrangement occurs by inversion, generating a signal joint and coding joint that remain in the chromosome (Fig. 1a). pMX-INV also has an IRES-human CD4 cDNA cassette that permits the flow cytometric purification of cells containing chromosomal pMX-INV integrants (22).

Induction of Rag in wild-type abl pre-B cells leads to robust pMX-INV recombination (Fig. 2a) (22). Most of the rearrangement products are coding and signal joints, with hybrid joint formation being very rare (Fig. 2) (22). However, high levels of pMX-INV hybrid joints form after induction of V(D)J recombination in Atm-deficient abl pre-B cells (Fig. 2) (22). Sequence analyses revealed that these hybrid joints are diverse in nature with features, such as N and P nucleotide additions and nucleotide loss, suggestive of joining by NHEJ (22). Importantly, hybrid joints and coding joints in Atm-deficient abl pre-B cells form with similar kinetics and at similar levels, demonstrating that both are formed through efficient joining pathways in these cells.

Hybrid joints are formed at low levels in NHEJ-deficient abl pre-B cells

Atm could prevent hybrid joint formation through either NHEJ-dependent or NHEJ-independent pathways. To determine whether NHEJ-independent pathways can mediate hybrid joining in abl pre-B cells, we generated abl pre-B cells deficient in both core (Ku70) and noncore (Artemis and DNA-PKcs) NHEJ proteins and transduced these cells with pMX-INV. The induction of Rag in Ku70−/−, Artemis−−, and Scid abl pre-B cells led to DNA cleavage at pMX-INV and a marked accumulation of unrepaired coding ends, but low levels of coding joint formation, as would be expected given the NHEJ deficiencies (Figs. 2a, 3a, and 4a). Although pMX-INV hybrid joints also formed in Ku70−/−, Artemis−−, and Scid abl pre-B cells, the level of hybrid joint formation being very rare (Fig. 2) (22).

FIGURE 1. Schematic of pMX-INV and rearrangement products. a, Schematic showing the non-rearranged (NR), coding joined (CJ), and hybrid joined (HJ) configurations of the pMX-INV retroviral recombination substrate. The IRES-human CD4 cDNA (1-hCD4), the GFP cDNA and the recombination signals (triangles) are shown. The relative positions of the EcoRV (E) and NcoI (N) restriction sites are shown. Also indicated is the 3’ coding end (CE) generated by Rag cleavage. The relative positions of the pC and pB oligonucleotide primers used to amplify hybrid joints are shown. The relative position of the CE probe used for Southern blot analysis is also shown. b, Schematic of the different C4 probing DNA fragments generated by digestion of pMX-INV in different configurations (NR, CJ, HJ, and CE) with EcoRV or EcoRV/NcoI.
formation was approximately 20-fold lower than that observed in Atm-deficient cells (Fig. 2). Thus, NHEJ-independent pathways do mediate hybrid joint formation, although at very low levels, in NHEJ-deficient abl pre-B cells.

**FIGURE 3.** Hybrid joint formation in Atm-deficient cells is Artemis-dependent. *a,* Southern blot analyses of EcoRV digested, probe C4 hybridized genomic DNA from abl pre-B cells treated with STI571 for the indicated period of time (h). Results are representative of at least two experiments on each of two independent cell lines. *b,* PCR analysis of pMX-INV hybrid joint formation in the samples from *a* treated with STI571 for 48 h. The IL-2 gene PCR is shown as a DNA loading control. The PCRs were performed on serial 4-fold dilutions of genomic DNA.

**FIGURE 4.** Hybrid joint formation in Atm-deficient cells is dependent on the NHEJ protein Artemis

The low level of hybrid joint formation in NHEJ-deficient cells could be due to the suppression of NHEJ-independent pathways by Atm. In this regard, we reasoned that if Atm prevents hybrid joint formation primarily by modulating the function of NHEJ-independent pathways, then abl pre-B cells deficient in both Atm and the NHEJ protein Artemis (Artemis$^{-/-}$:Atm$^{-/-}$) should form hybrid joints at a level similar to that observed in Atm$^{-/-}$ cells. However, in striking contrast to Atm$^{-/-}$ cells, pMX-INV hybrid joints form at a very low level in Artemis$^{-/-}$:Atm$^{-/-}$ abl pre-B cells (Fig. 3). Thus, the efficient formation of hybrid joints in Atm-deficient abl pre-B cells is dependent on the NHEJ protein Artemis.

To confirm that Artemis is also required for hybrid joint formation in developing Atm-deficient lymphocytes in vivo, we assayed rearrangements at the TCR $\beta$ and $\delta$ loci in developing thymocytes. To this end, CD4$^+$CD8$^+$CD25$^+$ (CD25$^+$) thymocytes were purified by flow cytometric cell sorting from wild-type, Atm$^{-/-}$, Artemis$^{-/-}$, and Artemis$^{-/-}$:Atm$^{-/-}$ mice. In wild-type CD25$^+$ DN thymocytes, we find low levels of hybrid joint formation involving the V$\beta$14 and V$\delta$5 gene segments, which both rearrange by inversion (Fig. 5). In contrast, hybrid joints involving these V gene segments are readily detected in Atm$^{-/-}$ CD25$^+$ DN thymocytes, reaching levels that are 20-fold higher than those observed in wild-type CD25$^+$ DN thymocytes (Fig. 5). Importantly, these hybrid joints were not
hybrid joint formation observed in developing 5). Thus, as was observed in Ku70 or hybrid joint formation (Figs. 2 and 4). Notably, treatment of translation of unrepaired coding ends and a low level of coding and pre-B cells (Fig. 4). Thus, formation of hybrid joints in abl pre-B crease in hybrid joint formation that was observed in wild-type abl formed on serial 4-fold dilutions of genomic DNA. Results are represented on analysis of two mice from each genotype.

In this regard, treatment of wild-type abl pre-B cells with the Atm kinase inhibitor, KU-55933, resulted in an increase in pMX-INV hybrid joints and Vβ14-DJβ2 hybrid joints conducted on genomic DNA from CD25+ DN thymocytes purified from mice of the indicated genotypes. The IL-2 gene PCR is shown as a DNA loading control. The PCRs were performed on serial 4-fold dilutions of genomic DNA. Results are representative of analysis of two mice from each genotype.

detected in Artemis ΔΔ′:Atm ΔΔ′ CD25+ DN thymocytes (Fig. 5). Thus, as was observed in Atm ΔΔ′ abl pre-B cells, the robust hybrid joint formation observed in developing Atm ΔΔ′ lymphocytes is also dependent on Artemis.

Hybrid joint formation in Atm-deficient cells is dependent on Ku70 and DNA-PKcs

We wished to determine whether hybrid joint formation in Atm-deficient abl pre-B cells was dependent on NHEJ factors in addition to Artemis. Mice with combined deficiency in Atm and DNA-PKcs or Ku70 exhibit early embryonic lethality, precluding the generation of abl pre-B cells with combined deficiencies in Atm and either DNA-PKcs or Ku70 (26). Thus, an alternate approach was needed to determine whether DNA-PKcs and Ku70 are required for hybrid joint formation in cells deficient in Atm activity. In this regard, treatment of wild-type abl pre-B cells with the Atm kinase inhibitor, KU-55933, resulted in an increase in pMX-INV hybrid joint formation and an accumulation of unrepaired coding ends, demonstrating that inhibition of Atm kinase activity recapitulates the Atm ΔΔ′ phenotype. (Fig. 4) (22). Induction of Rag expression in Scid or Ku70 ΔΔ′ abl pre-B cells leads to an accumulation of unrepaired coding ends and a low level of coding and hybrid joint formation (Figs. 2 and 4). Notably, treatment of Scid or Ku70 ΔΔ′ abl pre-B cells with KU-55933 leads to a slight increase in unrepaired coding ends, possibly due to the blunting of Atm-dependent pathways that mediate cell death in response to unrepaired DNA DSBs (Fig. 4a). However, treatment of Scid or Ku70 ΔΔ′ abl pre-B cells with KU-55933 did not lead to the increase in hybrid joint formation that was observed in wild-type abl pre-B cells (Fig. 4). Thus, formation of hybrid joints in abl pre-B cells deficient in Atm kinase activity is dependent on the DNA-PKcs and Ku70 NHEJ factors.

Discussion

Our findings demonstrate that Atm functions to restrict hybrid joint formation through NHEJ-dependent pathways of DNA DSB repair. In this regard, we have shown that, like coding joints, the efficient generation of hybrid joints is dependent upon the DNA-PKcs and Ku70 NHEJ proteins in both Atm-sufficient and Atm-deficient lymphocytes (Fig. 6). Notably, the overall level of joining (coding and hybrid joints) in Atm-deficient cells is similar to the level of coding joint formation in wild-type abl pre-B cells. Thus, NHEJ activity per se is relatively intact during V(DJ) recombination in Atm-deficient lymphocytes, suggesting that the increased hybrid joint formation is due to defects in processes other than those that directly mediate joining.

Several findings are inconsistent with the notion that Atm performs a significant function in preventing NHEJ-independent hybrid joint formation through processes such as Rag-mediated transposition. The formation of hybrid joints by Rag-mediated transposition can occur through the joining of a signal end and a hairpin-sealed coding end, without a requirement for any additional proteins other than Rag-1 and Rag-2 (12, 13). Thus, hybrid joint formation by Rag-mediated transposition is not dependent upon the non-core NHEJ proteins Artemis and DNA-PKcs, whose primary known function during V(DJ) recombination is in opening hairpin-sealed coding ends (9, 27–29). However, in this study, we...
show that the majority of the hybrid joints that form in Atm-deficient cells are dependent on both DNA-PKcs and Artemis, consistent with the notion that their formation requires NHEJ hairpin opening activity.

Furthermore, hybrid joints formed by Rag-mediated transposition usually exhibit minimal joint diversity consisting of the addition of, at most, two P-nucleotides (8, 29, 30). However, sequence analysis of hybrid joints generated in Atm-deficient cells reveals the full spectrum of joint diversity including nucleotide loss and N- and P-nucleotide addition (22). It is conceivable that NHEJ-independent hybrid joint formation could also occur through an alternative end-joining pathway (14–18). However, when active, this pathway can mediate the efficient repair of Rag-mediated DSBs in DNA-PKcs-deficient cells, yet we find that most hybrid joints that form in Atm-deficient cells are dependent on DNA-PKcs. Together, our data clearly demonstrate that the majority of hybrid joints that form during V(D)J recombination in Atm-deficient lymphocytes require NHEJ activity. Thus, Atm functions to modulate the NHEJ repair of Rag-mediated DSBs in a way that significantly limits the formation of hybrid joints during rearrangements that occur by inversion.

During the repair of genotoxic DSBs, NHEJ generally rejoins the two DNA ends generated at a single DSB. However, during V(D)J recombination, NHEJ must join DNA ends that are generated at two distinct DSBs. In this regard, the coding ends from two distinct DSBs are joined to generate a coding joint, and the signal ends from these two breaks are joined to generate a signal joint. Atm could function in a way that directs the correct joining of DNA ends generated by Rag during lymphocyte Ag receptor gene assembly. However, the increased hybrid joint formation in Atm-deficient cells is only observed during rearrangements that occur by inversion, not during those that occur by deletion (22). Thus, if Atm directs the appropriate joining of DNA ends during V(D)J recombination, the requirement for this function is restricted to rearrangements that occur by inversion.

Rather than invoke distinct Atm-regulated pathways that prevent the accumulation of unpaired coding ends and the formation of hybrid joints exclusively during inversional rearrangements, we have proposed that both of these defects are due to a requirement for Atm to promote stability of DNA end complexes generated by Rag during lymphocyte Ag receptor gene assembly. However, the increased hybrid joint formation in Atm-deficient cells is only observed during rearrangements that occur by inversion, not during those that occur by deletion (22). Thus, if Atm directs the appropriate joining of DNA ends during V(D)J recombination, the requirement for this function is restricted to rearrangements that occur by inversion.

In addition, defects in the stability of postcleavage complexes in Atm-deficient cells would also lead to the loss of chromosomal coding ends. These coding ends could persist unpaired or be resolved aberrantly as chromosomal translocations and large chromosomal deletions and inversions. Thus, a requirement for Atm to stabilize DSB complexes in a way that facilitates their repair through the NHEJ pathway could explain both the accumulation of unpaired coding ends and the increase in hybrid joint formation observed in Atm-deficient lymphocytes.

This notion is supported by our current data demonstrating that hybrid joint formation in Atm-deficient cells is dependent on classical NHEJ. Atm could function directly to stabilize DNA DSB complexes after Rag-mediated DNA cleavage; however, it seems more likely that Atm promotes stability by activating downstream proteins that perform this function. In this regard, it is notable that inhibition of Atm kinase activity, with KU-55933, is sufficient to recapitulate the defects in V(D)J recombination observed in Atm cells.

The inhibition of hybrid joint formation during inversional rearrangements has important implications for efficient Ag receptor gene assembly. In this regard, inversional rearrangements involving V gene segments occur in the TCRβ and TCRγ loci. Moreover, in the Igλ locus, half of the Vκ to Jκ rearrangements occur by inversion. Hybrid joint formation during these rearrangements would result in large deletions of the TCR or Igλ locus that could severely limit, or even prevent, subsequent rearrangements that would generate functional Ag receptor genes. Thus, by inhibiting hybrid joint formation during inversional rearrangements, Atm functions to preserve the integrity of Ag receptor loci in a manner that optimizes the generation of functional Ag receptor genes.
