TLR9 Regulates TLR7- and MyD88-Dependent Autoantibody Production and Disease in a Murine Model of Lupus

Kevin M. Nickerson,*† Sean R. Christensen,*† Jonathan Shupe,*† Michael Kashgarian,‡ Daniel Kim,§⁺ Kevin M. Nickerson,*† Sean R. Christensen,*† Jonathan Shupe,*† Michael Kashgarian,‡ Daniel Kim,§⁺ Keith Elkon,§⁺ and Mark J. Shlomchik*†

Systemic lupus erythematous is characterized by the production of autoantibodies against nucleic acid-associated Ags. We previously found that Tlr7 was required for anti-Sm and Tlr9 for anti-chromatin autoantibodies. Yet, although Tlr7 deficiency ameliorated disease, Tlr9 deficiency exacerbated it. Despite the mechanistic and clinical implications of this finding, it has yet to be elucidated. In this study, we characterize MRL/lpr lupus-prone mice genetically deficient in Tlr7, Tlr9, both Tlr7 and Tlr9, or Myd88 to test whether Tlr7 and Tlr9 function independently or instead regulate each other. We find that disease that is regulated by Tlr9 (and hence is worse in its absence) depends on Tlr7 for its manifestation. In addition, although Tlr7 and Tlr9 act in parallel pathways on different subsets of autoantibodies, Tlr9 also suppresses the production of Tlr7-dependent RNA-associated autoantibodies, suggesting previously unrecognized cross-regulation of autoantibody production as well. By comparing disease in mice deficient for Tlr7 and/or Tlr9 to those lacking Myd88, we also identify aspects of disease that have Tlr- and Myd88-independent components. These results suggest new models for how Tlr9 regulates and Tlr7 enhances disease and provide insight into aspects of autoimmune disease that are, and are not, influenced by TLR signals. The Journal of Immunology, 2010, 184: 1840–1848.

The TLRs are a family of cell surface or endosomal pattern recognition receptors (1). Many of the known ligands for TLRs are microbial products such as bacterial LPS, but some TLR family members can be activated by nucleic acids that may be either pathogen or host derived (2, 3). TLR ligation results in the activation of transcription factors including NF-κB and IFN regulatory factor family members (4), which both activate the innate immune system and contribute to a robust adaptive immune response.

In addition to their role in the immune response to pathogens, TLRs have recently been implicated in autoimmunity (5, 6). Pioneering work demonstrated that B cells transgenically expressing a rheumatoid factor (RF) BCR can be activated ex vivo by immune complexes of anti-DNA or anti-RNA specificity (7, 8). This activation was dependent on Tlr9, the endosomal sensor for dsDNA, or Tlr7, an endosomal sensor for ssRNA; the signaling adaptor Myd88, which is downstream of both Tlr7 and Tlr9, was also required. Subsequent studies in RF BCR-transgenic animals confirmed and extended these findings in vivo (9). Other studies in anti-DNA and anti-RNA BCR-transgenic models demonstrated a similar requirement for Tlr9 or Tlr7, respectively, for activation of antinucleic acid B cells (10, 11). In contrast, the roles of TLRs in activating non-B cells, such as myeloid cells, in systemic autoimmunity are less clear. In vitro experiments implicate immune-complex, FcyR-dependent activation of dendritic cells (DCs) and plasmacytoid DCs, in promoting IFN-I and other cytokine secretion in a partially TLR-dependent fashion (12, 13). The roles of TLRs in DCs in vivo have not been specifically defined with respect to systemic autoimmunity.

Using the MRL/lpr murine model of systemic lupus erythematous, we previously examined the role of Tlr9 and Tlr7 in spontaneous disease in vivo using mice that lacked one or the other of these genes in all tissues. Tlr9 was required for endogenous anti-DNA Ab production (14, 15), a finding that has since been reproduced in other murine models of lupus (10, 16, 17). Unexpectedly, in Tlr9-deficient animals, despite the absence of anti-DNA Abs—the clinical hallmark of lupus—several parameters of disease, including hypergammaglobulinemia, lymphocyte activation, and glomerulonephritis, were significantly worsened (14, 15). In contrast, Tlr7 deficiency had no effect on anti-DNA Abs but instead prevented the appearance of anti-Sm autoantibodies in the MRL/lpr model (15). Disease phenotypes were partially ameliorated in the absence of Tlr7 despite the continued presence of anti-DNA and anti-nucleosome Abs. The discovery of a paradoxical and unique regulatory role for Tlr9 in lupus was surprising and has important implications for the design of clinical strategies as well as for our understanding of the mechanisms of disease initiation and propagation. So far, there has been no additional insight into how Tlr9 might play a regulatory role. Indeed, this finding raised a major question. Because Tlr7 and Tlr9 are homologous receptors expressed in similar tissues with (as far as is known) identical signaling pathways, how is it that the lack of either of these two genes results in opposite effects on immune activation and global disease?

One hypothesis is that Tlr7 and Tlr9 work in parallel, independent pathways. This would be consistent with their apparent parallel effects on distinct subsets of autoantibodies (10, 11, 15). In this view, divergent disease outcomes might arise from unsuspected differences in signaling pathways and/or from expression in different tissues at different times coupled with differential...
exposure to ligands. In contrast, it is possible that Tlr7 and Tlr9 are operating in series, with signals mediated by one influencing the other either directly or indirectly. One model of Tlr9 and Tlr7 interdependency postulates that Tlr9-dependent anti-chromatin Abs are important in the clearance of cellular debris, which in turn contain the ligands for both Tlr9 (i.e., DNA-related) and Tlr7-dependent (i.e., RNA-related) activation (18–20). In the absence of Tlr9, such Abs would be missing, leading to overstimulation of Tlr7 as a result of excess ligand. A second model postulates a direct interaction, with Tlr9 regulating signals via Tlr7 within the same cell. This could occur whether there were competition for downstream signaling components and/or whether Tlr9 signals induced expression of genes that counterregulated both Tlr9 and Tlr7 signals (21). The first step in understanding the roles of Tlr7 and Tlr9 and their interactions is to determine, genetically, whether one acts upstream of the other or whether they operate in parallel. To investigate this, we generated cohorts of mice simultaneously deficient in both Tlr7 and Tlr9, and we report on their phenotype and the implications for how Tlr7 and Tlr9 regu-
late autoimmunity in divergent directions.

In addition, though the absence of Myd88 ameliorates disease and reduces autoantibodies (8, 22), whether in regulating lupus it acts only downstream of Tlr7 and Tlr9 or rather has additional upstream inputs, such as other Tlrs or IL-1/18, has not been addressed. Furthermore, it is not known whether all immune activation and disease in the MRL/lpr model is dependent on Myd88/Tlr9 signals or whether additional innate immune receptor families or other factors also contribute. To address these issues, we produced backcrossed mice deficient in the adaptor Myd88 and compared them to the mice doubly deficient for Tlr7 and Tlr9. In this aspect of the study, we found that although Tlr7 and Tlr9 are important upstream inputs for Myd88, the control of autoimmunity by innate immunity is more complex than anticipated, with evidence for Tlr7/Tlr9-independent components as well as Myd88-independent aspects of disease.

Materials and Methods

Mice

To generate a cohort including Tlr7−/− Tlr9−/− mice and littermates for comparison, previously described Tlr9−/− and Tlr7−/− mice on the lupus-prone MRL/MpJ background (15) were intercrossed by standard breeding techniques. To simplify the breeding strategy, given that Tlr7 is known MRL lupus susceptibility loci (23–26). Mice were analyzed at 16 wk of age, except where indicated, because of the previously reported consistent with other reports by our group and others (8, 22).

To generate autoantibodies and anti-ENA Abs, we used a cohort of mice deficient in both Tlr7 and Tlr9, and we report on their phenotype and the implications for how Tlr7 and Tlr9 regulate autoimmunity in divergent directions.

In addition, though the absence of Myd88 ameliorates disease and reduces autoantibodies (8, 22), whether in regulating lupus it acts only downstream of Tlr7 and Tlr9 or rather has additional upstream inputs, such as other Tlrs or IL-1/18, has not been addressed. Furthermore, it is not known whether all immune activation and disease in the MRL/lpr model is dependent on Myd88/Tlr9 signals or whether additional innate immune receptor families or other factors also contribute. To address these issues, we produced backcrossed mice deficient in the adaptor Myd88 and compared them to the mice doubly deficient for Tlr7 and Tlr9. In this aspect of the study, we found that although Tlr7 and Tlr9 are important upstream inputs for Myd88, the control of autoimmunity by innate immunity is more complex than anticipated, with evidence for Tlr7/Tlr9-independent components as well as Myd88-independent aspects of disease.

Materials and Methods

Mice

To generate a cohort including Tlr7−/− Tlr9−/− mice and littermates for comparison, previously described Tlr9−/− and Tlr7−/− mice on the lupus-prone MRL/MpJ background (15) were intercrossed by standard breeding techniques. To simplify the breeding strategy, given that Tlr7 is known MRL lupus susceptibility loci (23–26). Mice were analyzed at 16 wk of age, except where indicated, because of the previously reported consistent with other reports by our group and others (8, 22).

To generate autoantibodies and anti-ENA Abs, we used a cohort of mice deficient in both Tlr7 and Tlr9, and we report on their phenotype and the implications for how Tlr7 and Tlr9 regulate autoimmunity in divergent directions.

In addition, though the absence of Myd88 ameliorates disease and reduces autoantibodies (8, 22), whether in regulating lupus it acts only downstream of Tlr7 and Tlr9 or rather has additional upstream inputs, such as other Tlrs or IL-1/18, has not been addressed. Furthermore, it is not known whether all immune activation and disease in the MRL/lpr model is dependent on Myd88/Tlr9 signals or whether additional innate immune receptor families or other factors also contribute. To address these issues, we produced backcrossed mice deficient in the adaptor Myd88 and compared them to the mice doubly deficient for Tlr7 and Tlr9. In this aspect of the study, we found that although Tlr7 and Tlr9 are important upstream inputs for Myd88, the control of autoimmunity by innate immunity is more complex than anticipated, with evidence for Tlr7/Tlr9-independent components as well as Myd88-independent aspects of disease.
performed ELISAs to quantitate autoantibodies to defined autoantigens. Anti-nucleosome autoantibodies were significantly reduced in the absence of Tlr9 (Fig. 2A). The residual anti-nucleosome activity observed in Tlr9-deficient animals was further reduced in Tlr7⁻/- Tlr9⁻/⁻ mice. Anti-nucleosome Abs were also significantly reduced in Myd88⁻/⁻ mice (Fig. 2B). These data suggest that Tlr9 and Myd88 are required for the majority of spontaneous anti-nucleosome Ab formation in vivo, whereas intact Tlr7 permits a low level of anti-nucleosome Ab to develop.

Next, we examined serum autoantibodies to RNA-associated proteins, such as Sm, a component of the nuclear pre-mRNA spliceosome (30, 31). At 16 wk of age, few animals had detectable anti-Sm Abs; however, the frequency and titer of anti-Sm were significantly elevated in mice lacking Tlr9 (Fig. 2C). By 24 wk of age, a greater proportion of wild-type MRL/lpr mice had developed anti-Sm, but mice lacking Myd88 did not develop significant anti-Sm titers (Fig. 2D). Analysis of an independent cohort of 24-wk-old Tlr7-deficient mice showed that anti-Sm Abs were dependent on Tlr7 (Supplemental Fig. 1), consistent with previous reports on a younger cohort (15). Similarly, Abs to ribosomal P Ag (32) were elevated in the absence of Tlr9 unless Tlr7 was also absent (Fig. 2E), implying that intact Tlr9 suppresses the development of Abs to these Tlr7-dependent RNA-associated proteins. Anti-ribosomal P Ag Abs were absent in 24-wk-old Myd88-deficient mice (Fig. 2F), although low titers were detectable in 16-wk-old Tlr7⁻/- Tlr9⁻/⁻ mice (Fig. 2E), suggesting that Myd88-dependent pathways in addition to Tlr7 or Tlr9 may also contribute to the production of anti-ribosomal P Abs.

Autoantibodies reactive to RNA itself (28) were significantly reduced when Tlr9 was absent (Fig. 2G). These autoantibodies were further reduced when both Tlr7 and Tlr9 were absent; intriguingly, these data suggest that Tlr7 may be capable of activating anti-RNA B cells to some extent when Tlr7 is absent, particularly considering that Tlr7-dependent HEp-2 cytoplasmic staining was increased in Tlr9-deficient animals (Fig. 1B). Production of anti-RNA Abs required Myd88 (Fig. 2H), as expected.

Finally, we measured titers of anti-IgG2a RF autoantibodies (33). Interestingly, although absence of either Tlr7 or Tlr9 alone had no significant impact on RF titers, these titers were significantly reduced in Tlr7⁻/- Tlr9⁻/⁻ (Fig. 2I) and Myd88-deficient (Fig. 2J) mice. These results suggest that nucleic acid-containing immune complexes are an important immunogen for RF B cells in vivo, as has been shown artificially in vitro (7, 8). However, both Tlr7⁻/- Tlr9⁻/⁻ and Myd88⁻/⁻ MRL/lpr mice had significantly greater levels of RF than did age-matched nonautoimmune BALB/c controls, suggesting that both Myd88-dependent and Myd88-independent pathways contribute to the production of these autoantibodies, presumably through immune complexes that do or do not contain nucleic acids and/or through the activation of Myd88-independent nucleic acid sensors (34).

**Immune activation is regulated by TLR7, TLR9, and MyD88**

Activated immune cells accumulate in MRL/lpr mice, resulting in increased serum Ig titers, splenomegaly, tissue damage, and lymphadenopathy (35). To assess global immune activation, we measured serum Ig by ELISA. As previously observed, total serum Ig was significantly elevated in mice deficient in Tlr9 compared with Tlr9⁺/+ MRL/lpr mice (Fig. 3A). Ig concentrations were lower in Tlr7⁻/- Tlr9⁻/⁻ and Myd88⁻/⁻ MRL/lpr mice than in Tlr7⁺/+ mice, indicating that the stimulatory effect of Tlr9 deficiency requires intact Tlr7. Similarly, mice deficient in Myd88 also had reduced serum Ig concentrations at 16 and 24 wk of age (Fig. 3B). Importantly, however, although Ig titers were reduced in Tlr7⁻/- Tlr9⁻/⁻ and Myd88⁻/⁻ mice, they remained significantly higher than in age-matched BALB/c controls. Moreover, the presence of high IgG

**FIGURE 1.** ANAs are absent in mice lacking Myd88 or both Tlr9 and Tlr7. A, Representative HEp-2 ANA staining from serum of 16-wk (Tlr) or 24-wk (Myd88) old MRL/lpr mice of the indicated genotypes. Arrows indicate mitotic chromatin staining. B and C, HEp-2 slides were scored for intensity of nuclear (○) and cytoplasmic (●) staining patterns. Data are represented as mean ± SEM. Statistics were calculated by two-tailed Mann-Whitney U test. *p < 0.05; **p < 0.01; ***p < 0.001. D and E, HEp-2 slides were scored for the presence or absence of mitotic chromatin staining. Previously we observed an increased frequency of cytoplasmic-staining autoantibodies when Tlr9 was absent (15). To evaluate this phenomenon, we scored HEp-2 slides for the intensity of cytoplasmic staining (Fig. 1B, ●). Cytoplasmic staining was increased in both frequency and intensity in mice lacking Tlr9. However, the cytoplasmic staining was reduced in both Tlr7⁺/- Tlr9⁻/⁻ and Tlr7⁻/- Tlr9⁻/⁻ mice, suggesting that anti-cytoplasmic autoantibodies are Tlr7 dependent regardless of the Tlr9 genotype. Cytoplasmic staining was more prevalent in 24-wk than 16-wk-old mice and was significantly reduced in the absence of Myd88 (Fig. 1C, ●). Thus, Tlr9 suppresses Tlr7-dependent and Myd88-dependent anti-cytoplasmic Abs.

The staining of mitotic chromosomes in the HEp-2 assay indicates the presence of anti-chromatin autoantibodies (Fig. 1A, arrows). In agreement with prior results (15), these autoantibodies were Tlr9 dependent but not Tlr7 dependent (Fig. 1D); they were also absent in Myd88-deficient mice (Fig. 1E). Overall, these data revealed that HEp-2 staining autoantibodies of all types in the serum of MRL/lpr mice were reduced to near-background levels when both Tlr7 and Tlr9, or their signaling adaptor Myd88, were absent.

Although it has the advantage of detecting autoantibodies binding to native structures, the HEp-2 assay provides limited qualitative information about the identity of these autoantigens. Therefore, we performed ELISAs to quantitate autoantibodies to defined autoantigens.
titers in Tlr7−/−Tlr9−/− and Myd88−/− mice indicates that the markedly reduced amounts of selected serum autoantibodies in these mice (Figs. 1, 2) is not due to a nonspecific defect in B cell activation and Ig class switch.

Additionally, we measured concentrations of individual IgG isotypes. Serum IgG2a, IgG2b, and IgG3 were all elevated in Tlr9−/− mice (Fig. 3C, 3E, and Supplemental Fig. 2) as previously reported (15) but were reduced to concentrations below those of Tlr-intact MRL/lpr mice when Tlr7 was also absent. Hence, the hypergammaglobulinemia of Tlr9-deficient mice was again dependent on Tlr7. Amounts of each IgG isotype were also reduced in Myd88-deficient animals (Fig. 3D, 3F, and Supplemental Fig. 2). Nonetheless, titers of individual IgG isotypes remained markedly elevated in Tlr7−/−Tlr9−/− and Myd88−/− mice in comparison with BALB/c controls.

We also measured selected serum cytokines in a cohort of 13- to 17-wk old-animals (n ≥ 5, except n = 3 for Myd88−/−). There were no significant differences, as measured by cytometric bead assay, among the groups in the concentrations of IL-6, IL-10, IL-12, IL-23, and TNF-α (data not shown). A serum ELISA assay also did not reveal any differences in IFN-α concentrations in this cohort, although amounts in almost all mice were near the limits of detection (data not shown).

Tlr9−/− mice had significantly exacerbated splenomegaly and lymphadenopathy compared with Tlr9-intact littermates (Fig. 4A). However, this was ameliorated in mice also lacking Tlr7, indicating
Kidney disease is reduced in absence of Tlr7 and Tlr9 or Myd88

Aged MRL/lpr mice develop severe kidney disease characterized by glomerulonephritis and interstitial infiltrates composed of lymphocytes and monocyes, with resultant proteinuria (36). Proteinuria was significantly elevated in the Tlr9−/− mice but reduced in Tlr7−/− Tlr9−/− mice compared with the Tlr-intact controls (Fig. 6A). The elevated proteinuria in Tlr9−/− mice was dependent on Tlr7, because it was absent in the Tlr7−/− Tlr9−/− group. Proteinuria was also significantly reduced in 24 wk old Myd88−/− mice (Fig. 6B).

Glomerulonephritis was significantly more severe in Tlr9−/− mice at 16 wk compared with controls (Fig. 6C). This exacerbated glomerulonephritis required Tlr7, because it was not observed in the Tlr7−/− Tlr9−/− group. Glomerulonephritis was also reduced in the absence of MyD88 (Fig. 6D). Notably, interstitial infiltrates were not significantly changed in the absence of either Tlr7 or Tlr9 alone but were significantly reduced when both Tlrs or Myd88 were absent (Fig. 6E, 6F), suggesting that either Tlr7 or Tlr9 is sufficient to promote interstitial disease, but that one or the other is required.

Dermatitis incidence, but not severity, is reduced in absence of Myd88

MRL/lpr mice develop dorsal skin lesions as they age, as well as a facial rash, loss of whiskers, and degradation of the soft tissue of the ears (37, 38). Because few mice of any genotype had developed dermatitis at 16 wk of age, a separate group of MRL/lpr, Tlr7−/− Tlr9−/− and Myd88−/− mice were aged to 24 wk to evaluate skin disease. Although we did not observe significant sex-dependent differences in other aspects of disease (data not shown), dermatitis incidence and severity were greater in female mice than male mice of each genotype (Fig. 7A, 7B), and so males and females were analyzed separately. The incidence of dermatitis (skin score > 1) was not different between MRL/lpr and Tlr7−/− Tlr9−/− MRL/lpr mice, indicating that skin disease does not require Tlr7 or Tlr9. However, dermatitis incidence was reduced in mice

that Tlr7 is required for the increased spleen and lymph node weight observed in the Tlr9-deficient animals. Although spleen and lymph node weights were also similar in weight in both Myd88+/+ and Myd88−/− animals at 16 wk of age, by 24 wk their weights had increased significantly in Myd88−/− but not Myd88−/− animals (Fig. 4B). Both Tlr7+/− Tlr9−/− and Myd88−/− MRL/lpr mice had larger spleens and lymph nodes than age-matched BALB/c controls.

To determine the cellular composition of the spleens, we enumerated various cell populations by flow cytometry. In Myd88−/− mice, we found a 2- to 3-fold reduction in the number of T cells, plasmacytoid, and conventional DCs and CD11b+CD11c− macrophages (data not shown). Conversely, the increased spleen weight observed in Tlr7+/− Tlr9−/− mice compared with other groups was attributed to an expansion of T cells, especially CD45R+CD90+ cells, as well as an increase in CD11c+ cells, whereas B cell numbers increased only slightly (data not shown).

We evaluated CD4+ T cells for the expression of the activation markers CD44 and CD62L (Fig. 5A). Tlr7+/− Tlr9−/− mice had more CD44+CD62Lhigh activated and CD44+CD62Llow memory T cells compared with Tlr9-intact or Tlr9−/− groups (Fig. 5B). Again, when Tlr7 was also absent, the expansion of activated and memory T cells was not observed. Similarly, 16- and 24-wk old Myd88−/− animals had an increase in the number of activated and memory CD4 T cells compared with Myd88-deficient animals (Fig. 5C). No differences were observed among any of the groups in Foxp3+ regulatory T cells as a proportion of CD4+ cells (data not shown).
lacking Myd88 (Fig. 7A), suggesting that there may be a role for other TLR family members or signaling through the IL-1R family of cytokine receptors, which have been implicated in psoriasis and other dermatological diseases (39, 40). Notably, although the number of Myd88-deficient mice developing dermatitis by 24 wk was reduced, animals that did develop dermatitis had lesions of similar severity to Myd88-intact mice (Fig. 7B). The residual disease in Myd88-deficient animals indicates that MyD88 is not required for dermatitis, although it enhances its incidence.

Aged Tlr7<sup>−/−</sup> Tlr9<sup>−/−</sup> mice do not develop autoantibodies or lupus-like disease

To determine whether the mild disease and the absence of autoantibodies observed in 16-wk-old Tlr7<sup>−/−</sup> Tlr9<sup>−/−</sup> MRL/lpr mice represented a delay in the progression of disease or an absolute requirement for Tlr-dependent signals, we aged a cohort of male and female Tlr7<sup>−/−</sup> Tlr9<sup>−/−</sup> MRL/lpr mice to 48 wk of age and evaluated serum autoantibodies and other disease parameters. Because all Tlr9<sup>−/−</sup> and most Tlr-intact MRL/lpr mice died before 48 wk, it was not possible to provide age-matched controls of these genotypes for direct comparison. Nonetheless, nine of nine Tlr7<sup>−/−</sup> Tlr9<sup>−/−</sup> mice were negative in the HEp-2 and anti-nucleosome ELISA assays as late as 48 wk of age (data not shown). Five of nine animals were negative in the anti-Sm ELISA, whereas the remaining animals had levels near the lower limit of detection in the assay (~4 μg/ml Y12 equivalents.) Serum IgG concentrations ranged from 4.9 to 29.4 mg/ml, similar to the amounts observed in the 16-wk cohort, indicating that hypergammaglobulinemia did not become more severe with increasing age. Kidneys were evaluated by histology; two of nine mice had moderate glomerulonephritis (GN score of 2), whereas none had significant interstitial disease (data not shown). Survival of mice deficient in either Tlr7 or both Tlr7 and Tlr9 was slightly improved compared with Tlr-intact mice, although this difference was not statistically significant, given the small cohort size, we were able to analyze at this advanced age (Supplemental Fig. 3). Thus, albeit in a limited study, the effects of lack of both Tlr7 and Tlr9 are persistent in substantially ameliorating serologic, histologic, and clinical signs of lupus.

Discussion

In previous studies, we described the phenotypes of MRL/lpr lupus-prone mice lacking either Tlr7 or Tlr9. Tlr7 had no effect on ANA and anti-DNA Ab production, but disease was ameliorated when Tlr7 was absent (15). In contrast, Tlr9 was essential for anti-DNA Abs, the clinical hallmark of lupus, but disease was unexpectedly exacerbated in Tlr9-deficient animals (14, 15). To better understand the interaction of these genes in murine lupus and resolve the role of Tlr9 in disease, we generated and analyzed cohorts of mice simultaneously deficient in both Tlr genes, along with Tlr7- and Tlr9-deficient mice for direct comparison. Moreover, we analyzed animals deficient in the signaling adaptor Myd88, which is required for signaling through both Tlr7 and Tlr9, as well as other Tlr genes and the Il1r family of cytokine receptors.

Although the design of our current experiments was straightforward, we were able to reach a number of important conclusions that significantly advance our knowledge of how Tlr genes and Myd88 both promote and regulate autoimmunity, as well as the

FIGURE 5. Activation of CD4 T cells. A, Representative FACS staining of CD45R<sup>−</sup>CD90.2<sup>+</sup>CD4<sup>+</sup> T cells from 16-wk-old Myd88<sup>−/−</sup> and Myd88<sup>−/−</sup> MRL/lpr mice. B and C, Number of CD45R<sup>−</sup>CD90.2<sup>−</sup>CD4<sup>+</sup> cells with naive (CD44<sub>low</sub>CD62L<sub>high</sub>, left), activated (CD44<sub>high</sub>CD62L<sub>low</sub>, middle) and activated/memory (CD44<sub>high</sub>CD62L<sub>low</sub>, right) phenotypes. Statistics were calculated by two-tailed Mann-Whitney U test. *p < 0.05; **p < 0.01.
relationships among Tlr7, Tlr9, and Myd88. First, although we previously knew that Tlr7 and Tlr9 largely controlled independent sets of autoantibodies and were in this sense acting in parallel, we discovered that Tlr9 suppresses Tlr7-dependent anti-RNA associated autoantibodies. Thus, Tlr9 acts as an upstream regulator for this class of Ab. Second, for almost all elements of disease for which we previously ascribed a regulatory role for Tlr9, the exacerbated disease was no longer observed when Tlr7 was also absent. This implicates Tlr7 as functioning downstream of Tlr9 in promoting disease and again supports a model in which the Tlrs genetically interact. Taken together, these observations provide insight into the mechanism of the opposing effects of Tlr7 and Tlr9.

Furthermore, we demonstrated that Tlr7 and Tlr9 together were sufficient to account for the primary diagnostic characteristic of lupus, the ANA. The phenotypes of the Tlr7<sup>+/−</sup> Tlr9<sup>−/−</sup> mice were identical in this respect to the Myd88-deficient animals, establishing that no other Tlr, or other innate immune sensor, is involved in producing the ANA in MRL/lpr mice. A very recent report on the phenotype of Unc93b-deficient animals on the B6/lpr background similarly demonstrated reductions in antichromatin and RF, presumably due to effects of this gene on signaling from endosomal TLRs (41). Despite the exclusive influence of these receptors on autoantibodies, we discovered that there remained substantial aspects of disease that were independent of both Tlr and Myd88. Thus, some aspects of systemic autoimmunity either depend on other innate immune receptors yet to be identified or, in contrast to current theory (42), lack any need for innate stimulation. These findings support the need for further investigation to determine the roles of other innate receptors in systemic autoimmunity, as might be suggested by reports of TLR-independent DNA sensing pathways that lead to autoimmunity and IFN-I production (43, 44), including the pathway downstream of Trex1 (45).

On the basis of our findings, we propose a model by which the loss of Tlr9 exacerbates Tlr7-dependent disease. This might occur in cis, in trans, or both. In a cis-interaction model, the presence of Tlr9 directly inhibits the activity of Tlr7 within a single cell. This might occur through competition for rate-limiting downstream signaling components, such as Myd88 and others, so that (for example) a B cell with anti-RNA specificity could be more responsive to Tlr7 signals when Tlr9 is absent. A recent report (46) on cell lines suggested that a truncated form of the Unc93b gene product could differentially interact with TLR7 and TLR9, providing a potential mechanism by which TLR9 could inhibit TLR7. However, the authors could not find a naturally occurring truncated protein. Alternatively, Tlr9 signaling may be constitutively active to some degree because of both the abundance and stability of DNA ligands and the steady expression of the receptor and may tonically induce counterregulatory molecules, which in turn would inhibit subsequent signals via Tlr7. When Tlr9 is not expressed, such inhibitors would be absent, leading to greater stimulation via Tlr7. In support of this model, there is at least one report that overexpression of TLR9 can inhibit TLR7 signals in cell lines (47).

In a fundamentally different way, the interactions between Tlr7 and Tlr9 might occur in trans, through the effects of Tlr-dependent cytokine production, the activities of the different subsets of autoantibodies themselves or competition for niches for antibody-forming cells (48). In a limited survey of inflammatory cytokines, however, we did not observe differences in serum concentrations among the groups. In one particular model of trans-regulation, anti-DNA Abs controlled by Tlr9 are important in the clearance of pathogenic cellular debris, which contain ligands for both Tlr9 and Tlr7 (18–20, 49, 50). In the absence of Tlr9, Tlr7 might be overstimulated because of increased availability of its ligands. To
distinguish among these *cis* and *trans* models will require lineage-specific deletion of the *Tlr* genes, especially *Tlr9*, so that the role of *Tlr* in generating autoantibodies can be distinguished from effects in other cells and on end-organ damage. The key observation made in this study that *Tlr9* regulates *Tlr7*-dependent disease provides a framework and strong rationale for such future studies.

Although we found that autoantibody production was mediated by parallel *Tlr*-dependent pathways, our findings in the doubly-deficient mice also revealed a previously unappreciated degree of overlap between the DNA- and RNA-associated specificities. This in turn has implications for how *Tlrs* recognize self-Ags in vivo. It is likely that the in vivo autoantigens, which include dead and dying cells and cellular debris, are heterogeneous mixtures containing both *Tlr9* and *Tlr7*-activating DNA and RNA components (18, 20, 49, 50). If that is the case, then the low level of anti-nucleosome autoantibody in the single *Tlr9* knockouts and the residual anti-RNA activity in *Tlr7* knockouts may be explained by activation of the opposite specificity of *Tlr* by the mixed Ag; in the absence of both *Tlr7* and *Tlr9*, or the common adaptor Myd88, neither type of autoantibody is generated. A second possibility is that the paradigm of *Tlr7* recognizing exclusively RNA and *Tlr9* recognizing exclusively DNA may be incomplete; indeed, TLR7 can bind to DNA (51). Either of these possibilities would be consistent with our data, as well as with findings in transgenic BCR systems of autoimmune activation (11). For example, anti-nucleosome immune complex activation of RF B cells was shown to be only partially dependent on either *Tlr9* or *Tlr7* alone, although it was abrogated in the absence of both *Tlr* or Myd88 (9).

Mice lacking Myd88 were equivalent to the *Tlr7/9*-deficient animals in many respects, having nearly undetectable autoantibody titers and little disease, suggesting that *Tlr7* and *Tlr9* are required for the majority of disease in the MRL/*lpr* model and that other Myd88-dependent pathways are of less import. However, despite the lack of HEp-2-reactive autoantibodies in both *Tlr7/9*– and *Myd88*-deficient animals, both groups of mice developed dermatitis. The incidence of dermatitis was diminished in Myd88-deficient mice compared with *Tlr7/9*-deficient animals, suggesting that there may be a contribution of other Myd88-dependent pathways to development of dermatitis. In addition to its role in *Tlr* signaling, Myd88 is required for signal transduction downstream of the II1r family of cytokine receptors, which have been implicated in psoriasis and other dermatological conditions (39, 40). Nonetheless, the dermatitis phenotype had a substantial Myd88-independent component. Increased spleen and lymph node weights and hypergammaglobulinemia were also still present in both *Tlr7/9* or *Myd88*-deficient animals compared with a nonautoimmune strain. This could in part be caused by the *lpr* mutation of *Fas*, which prevents Fas/Fas ligand-mediated apoptosis (52). Importantly, however, the *lpr* mutation was not sufficient to provoke development of specific lupus autoantibodies or significant kidney disease in the absence of *Tlr7* and *Myd88*-mediated signaling, consistent with the notion that the *lpr* mutation is an accelerator of disease mediated by other lupus-susceptibility loci in the MRL background. This role of Fas-deficiency has been confirmed in numerous studies of MRL mice deficient in key genes or cell types in the immune system (53–57). Taken together, these findings do suggest that Myd88-dependent innate signaling is not sufficient to account for all aspects of systemic autoimmune disease. Indeed, such results point to the possibility of other innate signaling mechanisms in stimulating certain types of autoimmunity.

Given the importance of nucleic acid recognition in a variety of systemic autoimmune syndromes, other recently-described pattern recognition receptors that recognize nucleic acids—including DAI, RIG-I, Mda5, and AIM2 (58–67)—might be playing unsuspected roles, either accounting for Myd88-independent aspects of disease or making contributions downstream of autoantibody production, which was largely dependent upon *Tlr7* and *Tlr9*. However, it is important to realize that even if *Tlr7* and/or *Tlr9* are essential for some aspects of disease and autoantibody production, this does not rule out an additional essential role for other nucleic-acid sensing pathways. Alternatively or in addition, residual aspects of disease in the *Tlr7*–/–*Tlr9*–/– and Myd88–/– groups may depend upon protein autoantigens, which are not nucleic acid dependent. Nonetheless, it is clear that *Tlr7* and *Tlr9* play very essential roles in most aspects of disease. Perhaps most importantly, our results demonstrate that the regulatory role of *Tlr9* is best understood in terms of regulating *Tlr7*-dependent signals. Work is underway to distinguish among the several possible ways in which this could occur; resolution will require the development of conditional alleles for *Tlr9* and *Tlr7* and their deployment in autoimmune models. Biochemical approaches will also be useful in testing some aspects of these models.

For the present, these findings have important therapeutic implications (68), as they suggest that inhibitors that target *Tlr7* should be beneficial, whereas those that target *Tlr9* alone may paradoxically exacerbate disease; however, inhibitors that target both may have even more efficacy. Indeed, studies of a synthetic inhibitor of both *Tlrs* in the MRL/*lpr* (69) and (NZB × NZW)F1 (70) models of lupus found significantly reduced lymphadenopathy and glomerulonephritis, as well as improved survival in treated animals.
