Neutralization of IL-9 Ameliorates Experimental Autoimmune Encephalomyelitis by Decreasing the Effector T Cell Population

Hongmei Li, Bardia Nourbakhsh, Bogoljub Ciric, Guang-Xian Zhang, and Abdolmohamad Rostami

Multiple sclerosis is a CD4+ T cell-mediated autoimmune disease affecting the CNS. Multiple sclerosis and its animal model, experimental autoimmune encephalomyelitis (EAE), have been thought to be Th1-mediated diseases. However, recent studies provide strong evidence that the major pathogenic T cell subsets in EAE are Th17 cells. IL-9, a hematopoietic growth factor, is considered to be a mediator of Th17 cells, but the precise mechanisms of its action are largely unknown. The present study was designed to investigate the role of IL-9 in autoimmune demyelination. IL-9 blockade with anti–IL-9 mAb inhibited the development of EAE, reduced the serum levels of IL-17, the CNS mRNA expression of IL-17, IL-6, IFN-γ, and TNF-α, and the myelin oligodendrocyte glycoprotein (MOG)-induced IL-17, IFN-γ secretion of lymphocytes. Furthermore, anti–IL-9 mAb in culture suppressed IL-17 production of MOG-reactive T cells and their potency in adoptive transfer EAE. These findings indicate that the protective effect of IL-9 blockade in EAE was likely mediated via inhibition of the development of MOG peptide-specific T cells, which in turn led to reduced infiltration of T cells into the CNS. Thus, anti–IL-9 mAb treatment may provide an effective therapeutic strategy against autoimmune diseases. *The Journal of Immunology*, 2010, 185: 4095–4100.

Experimental autoimmune encephalomyelitis (EAE), a CD4+ T cell-mediated inflammatory demyelinating disease of the CNS, serves as a model of the human disease multiple sclerosis (MS) (1). EAE can be induced by immunization with myelin Ags or by adoptive transfer of myelin-reactive CD4+ T cells into naive recipients.

Although there is evidence linking CD4+ T cells such as Th17 (2, 3), Th1 (4, 5), and Th9 cells (6) with the pathogenesis of EAE, the precise contribution of these T cell subtypes or their associated cytokines is still unclear. There is growing evidence that clinically similar forms of autoimmune demyelinating disease can be driven by myelin-specific T cells of distinct lineages, with different degrees of dependence on IL-17A production by Th17 cells, to achieve their pathological effects (2, 7–9). Moreover, IL-17–deficient mice have been reported to develop EAE with delayed onset and reduced severity (10, 11). In humans, Th17 cells have been identified in the CNS of patients with MS (12, 13). The pathogenic role of IL-17 in MS has been suggested in numerous studies (14–16). Because IL-17 signaling is important for the production of various chemokines from fibroblasts and epithelial cells (14–16), which attract APCs to the CNS, resulting in demyelination, the suppression of the development or the proliferation of Th17 cells may represent a promising therapy for MS. However, recently, Axtell et al. (4) showed regular susceptibility to EAE induction in the absence of IL-17A and IL-17F, as well as suppression of EAE in the presence of unaltered Th17 responses, and they suggested that both Th1 and IL-17–producing CD4+ T cells are important for the development of EAE.

It has been demonstrated that IL-9 together with TGF-β can induce the differentiation of naïve CD4+ T cells into Th17 cells in vitro (17, 18), and that IL-9 produced by Th17 cells themselves amplifies Th17 development in a positive autocrine loop (17). Thus, IL-9 represents a potential target for the inhibition of Th17 development in vivo. Temporal blockade of IL-9 using neutralizing Ab may produce results inconsistent with those obtained in IL-9R–deficient mice, given that IL-9 acts as a hematopoietic growth factor and its complete absence may influence hematopoietic development (19, 20). Treatment with anti–IL-9 mAb has been reported in one study to be protective against EAE (17). However, in another study, IL-9R knockout mice were more susceptible to EAE than were wild-type mice (21), and they were partially resistant in another study (17).

Additionally, IL-9 inhibited lymphokine production by IFN-γ–producing CD4+ T cells (22), exogenous IL-9 reduced IFN-γ mRNA expression in PBMC from latent tuberculosis infection by 30%, and neutralization of IL-9 restored IFN-γ mRNA expression (23). Activation of naïve T cells in the presence of TGF-β and anti–IFN-γ significantly enhanced IL-9 production (24). These results suggest pleiotropic effects on effector CD4+ T cells. The role of IL-9 in the pathogenesis of MS/EAE thus remains unclear.

In the present study, we investigated the in vivo role of IL-9 in the development of T cells, particularly Th17 cells, in EAE, using an anti–IL-9 mAb, which has shown significant protective effect in other inflammatory diseases (25, 26). Our results show that early anti–IL-9 mAb treatment reduces encephalitogenic Th1 and Th17 cells and inflammatory myeloid cell invasion into the CNS.

Materials and Methods

Mice

C57BL/6 mice were obtained from The Jackson Laboratory (Bar Harbor, ME). For all experiments, 8- to 10-wk-old female mice were used. All animals were housed under specific pathogen-free conditions and animal protocols were approved by the Thomas Jefferson University Animal Care and Use Committee. Paralyzed mice were afforded easy access to food and water.

Induction of EAE

Mice were immunized s.c. with 200 μg myelin oligodendrocyte glycoprotein (MOG35–55) peptide emulsified in CFA and injected twice with pertussis toxin (27). The severity of EAE was monitored and graded on a scale of 0–5: 0, no disease; 1, limp tail; 2, hind limb weakness; 3, hind limb paralysis; 4, hind and forelimb paralysis; and 5, moribund and death.

Anti–IL-9 mAb treatment

Anti–IL-9 mAb (clone D9302C12: BD Pharmingen, San Diego, CA) was confirmed in vitro to have inhibitory effects upon IL-9 bioactivity (28). In a pilot study we sought to ascertain the optimal dose of anti–IL-9 mAb in vivo. In brief, anti–IL-9 mAb at doses of 0.3 mg, 1.2 mg, 4.8 mg (n = 3 in each group) or isotype-matched hamster IgG at a dose of 4.8 mg (n = 3) was injected i.p. once starting with day -1 of EAE induction. Blood from the orbital vein was obtained using a capillary tube on day 19. Anti–IL-9 mAb was measured by ELISA (eBioscience). We found that a dose of 0.3 mg is optimal (data not shown).

For IL-9 blockade, mice were i.p. treated with 0.3 mg hamster anti–IL-9 mAb (clone HA4/8, hamster IgG, BD Pharmingen) or isotype control I (clone Ha4/8, hamster Gig, BD Pharmingen) or anti–IL-9 mAb (clone D9302C12, hamster IgG; BD Pharmingen) every other day starting on day -1 postimmunization (p.i.). Other groups of mice received 10 ng rIL-9 (Akron Biotech, Philadelphia, PA) dissolved in 0.3 ml PBS daily beginning on the day of EAE induction.

CNS histology

Spinal cords were carefully dissected and immersion fixed in 4% formaldehyde in PBS (27). In brief, fixed tissues were embedded in paraffin wax and sections were cut from the mid-lumbar spinal cord (L3). Sections were stained with H&E or Luxol fast blue (myelin stain) for analyses of inflammation and demyelination, respectively. Slides were assessed in a blinded fashion for inflammation and demyelination as described previously (29, 30). Briefly, inflammation was scored as follows: 0, none; 1, a few inflammatory cells; 2, organization of perivascular infiltrates; and 3, increasing severity of perivascular cuffing with extension into the adjacent tissue. Demyelination was scored as follows: 0, none; 1, rare foci; 2, a few areas of demyelination; and 3, large (coalescent) areas of demyelination.

Isolation of CNS-infiltrating cells

Mice were perfused via the left atrium with glucose containing PBS, and spinal cords were removed. Mononuclear cells were isolated by digestion of the spinal cord homogenate with collagenase and DNAse, followed by Percoll gradient centrifugation. CNS homogenates were pooled for each treatment group prior to analysis. For flow cytometry analyses, these cells were incubated with Abs to murine CD11b, CD11c, CD4, CD45, CD8a, and B220 (all from BD Pharmingen). The absolute numbers for each population were calculated by multiplying the frequency of each population by the total number of cells isolated per treatment group.

Gene expression analysis by real-time PCR

Mice were sacrificed at the peak of actively induced EAE disease: IgG+ T cells, purified using magnetic bead separation kits (Miltenyi Biotec, Auburn, CA), were cultured with anti-CD3 (1 μg/ml) and anti-CD28 (1 μg/ml) Abs (BD Pharmingen), TGF-β (3 ng/ml), IL-6 (30 ng/ml), and anti–IL-4 (10 μg/ml) (all from Invitrogen) in the presence or absence of recombinant mouse IL-9 (10 ng/ml) (Akron Biotech), or anti–IL-9 mAb (100 ng/ml). Relative expression was calculated following the previously described protocol (27).

Adaptive EAE

Female 8- to 10-wk-old wild-type mice were immunized s.c. with 100 μg MOG35–55 containing 200 μg Mycobacterium tuberculosis H37Rv (Difco Laboratories, Detroit, MI) on day 0 and day 7. The immunized mice were treated with anti–IL-9 mAb (300 μg) once on days −1, 0, 2, 4, 6, 9, and 10 or with 20 mg IL-9 every day beginning on the day after injection. Control mice were treated with PBS. Lymph node cells were harvested on day 12 p.i. and cultured for 3 d in RPMI 1640 supplemented with 10% FCS, penicillin/streptomycin, t-glutatmine, HEPES, sodium pyruvate, and 2-ME. All cells were cultured in the presence of MOG35–55 (50 μg/ml) and IL-23 (10 ng/ml). After 72 h, cells were harvested, washed in PBS, and transferred to naive recipient mice (2 × 105 cells/mouse) via the tail vein. The mice were given two doses (250 ng/mouse) of pertussis toxin i.p. on days 0 and 2 after cell transfer. EAE disease induction was assessed as described above.

Intracellular cytokine staining

Draining lymph node cells were stimulated with 15 μg/ml MOG35–55 peptide for 72 h and restimulated with 50 ng/ml PMA and 750 ng/ml ionomycin for the last 4 h in the presence of 10 μg/ml brefeldin A. To analyze lymphocytes infiltrated into the CNS, spinal cords were removed as described above, followed by digestion with collagenase D (5.0 mg/ml; Roche Diagnostics, Indianapolis, IN). Cells were isolated by Percoll centrifugation as previously described (27) and surface-stained with Abs against CD4 (RM4-5; BD Biosciences, San Jose, CA), Intracellular cytokine staining and FoxP3 staining were performed as described previously (27, 31). Cells were analyzed by a FACSArray flow cytometer (BD Biosciences), and data obtained were analyzed by FlowJo software (Tree Star, Ashland, OR).

Recall response and T cell cytokine production

Spleens were taken from mice sacrificed 8 d after MOG35–55 immunization. Cells were gently dispersed through nylon mesh into a single-cell suspension, washed, and cultured at 106 cells/ml in complete RPMI (RPMI 1640 containing 10% heat-inactivated FCS [CSL, Parkville, Victoria, Australia], 2 mM L-glutamine, 100 U/ml penicillin, and 100 μg/ml streptomycin). Cells were either stimulated with MOG35–55 (15 μg/ml) or anti–CD3 (1 μg/ml) plus CD28 (1 μg/ml) or left without any exogenous stimuli. For proliferation, [3H]thymidine (1 μCi/well) was added at 60 h, and incorporation of thymidine in DNA was measured after 12 h by a Wallac 1450 MicroBeta TriLux liquid scintillation counter (PerkinElmer Life Sciences, Foster City, CA). Supernatants were collected at 72 h, and quantitative ELISA was performed for cytokines using paired Abs as recommended by the manufacturer (R&D Systems, Minneapolis, MN). For serum cytokine ELISA, blood was taken during the course of EAE via the tail vein, and serum samples were prepared using Z-Gel microtubes (Sarstedt, Newton, NC). Mouse IL-17 was detected with a Quantikine immunoassay kit (R&D Systems).

In vitro Th17 cell differentiation

Spleens were removed from naive mice and passed through a 100-μm cell strainer. Erythrocytes were lysed. CD4+ T cells, purified using magnetic bead separation kits (Miltenyi Biotec, Auburn, CA), were cultured with anti–CD3 (1 μg/ml) and anti–CD28 (1 μg/ml) Abs (BD Pharmingen), TGF-β (3 ng/ml), IL-6 (30 ng/ml), and anti–IL-4 (10 μg/ml) (all from Invitrogen) in the presence or absence of recombinant mouse IL-9 (10 ng/ml) (Akron Biotech), or anti–IL-9 mAb (100 ng/ml).

Statistical analysis

The two-tailed Student t test and the χ2 test were used to analyze the significance of results. Additionally, the Mann-Whitney U test was performed for nonparametric analyses. Differences were considered significant at p ≤ 0.05.

Results

Anti–IL-9 mAb treatment suppressed acute EAE

To determine the preventive efficacy of IL-9 blockade in autoimmune inflammatory disease, we tested the effect of anti–IL-9 mAb on EAE. Anti–IL-9 mAb treatment delayed the onset of clinical disease, ameliorated the severity of EAE (Fig. 1A), and reduced its incidence from 100 to 25% (Fig. 1B). This result is consistent with studies by Nowak et al. (17) demonstrating that targeted genetic disruption of IL-9R results in resistance to EAE.
The Journal of Immunology 4097

Treatment with anti–IL-9 mAb reduces CNS inflammation and demyelination

At the peak of EAE control, IgG-treated mice had extensive infiltration of mononuclear cells into the white matter of spinal cords (Fig. 2A–C). In contrast, cellular infiltration and demyelination were markedly reduced in spinal cords of anti–IL-9 mAb-treated mice, which was consistent with their decreased clinical scores (Fig. 2D–F). The difference between the pathological scores of control IgG-treated mice and anti–IL-9 mAb treatment groups of mice was highly significant (p < 0.01) (Fig. 2G).

Anti–IL-9 mAb-treated mice are devoid of CNS-infiltrated cells

To investigate the population of mononuclear cells that infiltrated into the CNS, we recovered mononuclear cells from spinal cords and stained them with CD4, CD8, B220, and CD11b Abs. At the peak of EAE, CD4+ T cells, CD8+ T cells, B cells, and macrophages were detected in control IgG-treated mice (Fig. 3A). In anti–IL-9 mAb-treated mice, the numbers of these cells were significantly reduced (Fig. 3A). Compared to control IgG-treated mice, the CNS of anti–IL-9 mAb-treated mice expressed significantly lower levels of IL-17, IL-6, IFN-γ, and TNF-α, but higher levels of FoxP3 mRNA (all p < 0.05–0.001; Fig. 3B).

Induction of MOG-specific T cells was suppressed in anti–IL-9 mAb-treated mice

To investigate whether the deficiency of CNS-infiltrating CD4+ T cells in anti–IL-9 mAb-treated mice was due to a T cell priming defect, we analyzed MOG35–55 peptide-specific CD4+ T cells from draining lymph nodes. In the lymphocytes prepared from inguinal lymph nodes at priming stage (8 d after Ag immunization), the development of Th17 cells as well as Th1 cells was significantly suppressed in anti–IL-9 mAb-treated mice compared with IgG-treated mice (Fig. 4A). The population of FoxP3+ Treg cells was not significantly changed in anti–IL-9 mAb-treated mice (Fig. 4B). To investigate the effect of IL-9 blockade on MOG35–55 peptide-specific cytokine production, we quantified the concentrations of cytokine levels secreted into the culture supernatant of lymphocytes from inguinal lymph nodes. We found that the production of IL-17 and IFN-γ was significantly suppressed in anti–IL-9 mAb-treated mice compared with control mice (Fig. 4C). Serum IL-17 level was also lower in anti–IL-9 mAb-treated mice (Fig. 4D). Additionally, anti–IL-9 mAb-treated T cells showed a significantly lower proliferative response to anti-CD3 stimulation and MOG35–55 peptide than did wild-type T cells (Fig. 4E). These results suggest that suppression of the differentiation of MOG35–55–reactive Th17 and Th1 cells by IL-9 blockade contributes to the protective effect against EAE.

Effect of anti–IL-9 mAb on Th17 differentiation in vitro

Given the role of IL-9 as a mediator of Th17-driven inflammatory disease (17), we next examined whether anti–IL-9 mAb had a direct effect on Th17 cell differentiation. Indeed, CD4+ T cells cultured with anti–IL-9 mAb showed significantly lower levels (3-fold decrease) of IL-17 production compared with wild-type CD4+ T cells when cultured with IL-6 plus TGF-β, suggesting that neutralizing IL-9 with anti–IL-9 mAb decreased the development of Th17 cells (Fig. 5A). IL-17 production was enhanced in the presence of recombinant IL-9 (Fig. 5A), suggesting an amplification loop in which IL-9 produced by Th17 cells participates in enhancing further differentiation of Th17 cells.
Anti–IL-9 mAb inhibits the generation of MOG-specific T cells in vivo

Because in vitro treatment of T cells with IL-9 mAb inhibited the differentiation of Th17 cells, we next investigated whether IL-9 mAb treatment is capable of inhibiting the generation of encephalitogenic T cells in vivo. Donor mice were treated with anti–IL-9 mAb or rIL-9; T cells from these donor mice were stimulated with MOG and IL-23 for 3 d in vitro and then transferred to recipient mice. In the control group, EAE was induced by adoptive transfer of enriched Th17 cells from donor mice that received only PBS. Mice that received MOG-specific T cells from IL-9 mAb-treated donor mice exhibited significantly less severe clinical signs and disease severity compared with the control EAE group (Fig. 5B). On the other hand, mice receiving enriched Th17 cells from recombinant IL-9–treated donor mice displayed a greater degree of disease severity compared with the control EAE group (Fig. 5B). These results suggest that IL-9 plays an important role in the generation of encephalitogenic T cells and that neutralization of IL-9 by mAb suppresses the production of encephalitogenic T cells in donor mice.

Discussion

CD4+ T cell subsets are important for understanding adaptive immunity in humans and in animal models of autoimmune disease. Our knowledge of CD4+ T cell differentiation has changed significantly, and new subsets continue to be recognized. Importantly, the recent discovery of the CD4+ T cell subset that produces IL-9 has expanded significantly (32). IL-9 has largely been regarded as a Th2 cytokine that plays a significant role in inflammatory disease (33, 34). Under certain conditions, IL-9 can cause pleiotropic effects on Th1 (23, 35), Th17 (21, 36), regulatory T cells (21, 37), and the Th9 subset (21, 23, 36), playing different roles depending on microenvironments. Biological actions of IL-9 in autoimmune disease are continuing to be refined. Focusing on how anti–IL-9 mAb affects MOG-specific CD4+ T cells in EAE will provide a better mechanistic understanding of the pathogenesis of various autoimmune diseases.

In this study, we demonstrated that administration of anti–IL-9 mAb treatment effectively suppressed disease incidence and severity of EAE. This was associated with significantly decreased levels of both MOG-specific Th1 and Th17 cells in the periphery and the CNS. Our results, together with the finding that humanized anti–IL-9 mAb can be treated repeatedly without antigenicity (38), suggest that anti–IL-9 mAb treatment may provide an effective therapeutic strategy against autoimmune diseases.

Infiltration of MOG35–55 peptide-specific CD4+ T cells into the CNS is an important step in EAE disease onset (39), and IL-9 has been reported to increase levels of expression of eotaxin, MIP-1α, and MCP-1, -3, and -5 in vitro and in vivo (40). These proteins have been suggested to be involved in the infiltration of lymphocytes through the blood–brain barrier (39). We therefore investigated the effect of anti–IL-9 mAb treatment against induction of EAE to elucidate the effect of IL-9 blockade against infiltration of activated lymphocytes into the spinal cord. We observed significantly reduced levels of inflammation and demyelination in the CNS of anti–IL-9 mAb-treated mice compared with control mice. Furthermore, anti–IL-9 mAb-treated mice exhibited a significant decrease in the absolute number of CD4+ T cells, CD8+ T cells, B cells, and macrophages infiltrating into the CNS. The absence of activated lymphocytes in the spinal cord of anti–IL-9 mAb-treated mice is likely to be mediated via the inhibition of the induction of MOG35–55 peptide-specific CD4+ T cells, including Th17, Th1 cells, and CD8+ T cells in the peripheral lymphoid tissue and also via the inhibition of infiltration of activated lymphocytes into the spinal cord.

Th17 cells directed against self-Ags cause severe autoimmune disease in mice, including EAE, nonobese diabetes, and collagen-induced arthritis (7, 41–43). These studies highlight the importance of understanding the regulation of Th17 cell development in autoimmune disease. In mice, autoantigen-specific Th17 cells have been shown to be the dominant pathogenic T cell subset in EAE (7, 44, 45). Previous studies have suggested a pathogenic role of IL-9 as a Th17-derived cytokine that can contribute to inflammatory disease (17). We provide evidence that functional blocking of IL-9 inhibited the differentiation of Th17 cells in vitro. We investigated the in vivo role of IL-9 in Th17 cell development in EAE, using an anti–IL-9 mAb and adoptive transfer EAE model. We showed that treatment with anti–IL-9 mAb effectively suppressed the incidence and severity of EAE. These results are consistent with previous studies using anti–IL-9 mAb treatment and IL-9R–deficient mice (17). Anti–IL-9 mAb-treated mice were devoid of mononuclear cells in the spinal cord. Importantly, treatment of donor mice with anti–IL-9 mAb also inhibited the generation of encephalitogenic T cells in vivo. In contrast, treatment of donor mice with recombinant IL-9 stimulated the generation of encephalitogenic T cells. As previously reported, IL-9 synergizes with TGF-β–differentiated naïve CD4+ T cells into Th17 cells in vitro (21). Our data support the importance of IL-9 in the differentiation of Th17 cells in vivo.

Furthermore, we found that anti–IL-9 mAb potently suppressed IL-17 production in culture. IL-23– plus anti–IL-9 mAb-treated
FIGURE 4. IL-9 blockade suppressed the induction of MOG35–55 peptide-specific T cells in peripheral lymphoid tissue. Intracellular staining of lymphocytes stimulated with MOG35–55 peptide is shown. Inguinal lymph node cells were recovered at day 8 p.i. All plots were gated on CD4+ T cells (A, B). C, IL-9 blockade suppressed the Ag-specific cytokine production of IL-17 and IFN-γ from lymphocytes. Splenocytes were recovered at the peak of disease after immunization and restimulated with 50 μm MOG35–55 peptide for 72 h. IL-17 and IFN-γ concentrations in the supernatants were determined. D, IL-9 blockade suppressed the serum level of IL-17. Mice were treated with anti–IL-9 mAb or control IgG, and serum samples were prepared at the peak of EAE after Ag immunization. IL-17 cytokine concentrations in the serum were analyzed. E, Spleen cells from MOG35–55–immunized mice obtained 8 d p.i. were restimulated ex vivo with MOG35–55 peptide (10 μg/ml) or anti-CD3 (1 μg/ml) and anti-CD28 (1 μg/ml). Proliferation was determined by [3H]thymidine incorporation as described in the Materials and Methods (n = 5/group). All p values were determined by using the Student t test. *p < 0.05; **p < 0.01; ***p < 0.001.

cells transferred significantly less severe EAE to naive animals. Importantly, anti–IL-9 mAb negated this effect, as demonstrated by a low level of IL-17 production in anti–IL-9 mAb-treated cultures. Consistent with these observations, rIL-9 in culture enhanced IL-17 production and the potency of MOG-reactive T cells to transfer EAE. These findings provide further evidence that suppression of adoptive transfer EAE by anti–IL-9 mAb is mediated by Th17 suppression.

In this study, we observed that anti–IL-9 mAb treatment decreased the induction of Th1 cells during the priming stage of lymph nodes, suggesting that IL-9 may regulate the differentiation of Th1 cells. In agreement with this, it has been reported that IL-9 can induce IFN-γ production and suppress Th2 immune response in Mycobacterium infections (35). The effects of IL-9 were not limited to antagonizing suppressive factors in Mycobacterium infections; it also amplified the stimulatory activities of IL-2 (35, 46) and IL-6 (35). This general stimulation of cytolytic activities was accompanied by and dependent on IFN-γ, as the IFN-γ message was up-regulated by IL-9 (35). Moreover, Ag- and IL-18–stimulated Th1 cells can strongly produce IFN-γ and IL-9 (47). Culturing of sorted IFN-γ+ Th1 cells with OVA, IL-2, and IL-18 in the presence of APCs led to an increase in IL-9, IL-13, IFN-γ, and GM-CSF, but not IL-4 production (48). These results indicate a positive correlation between IL-9 and Th1 cells. Thus, decreased Th1 response after anti–IL-9 treatment, together with suppressed Th17 cells, represents an important mechanism underlying anti–IL-9–induced EAE suppression.

When comparing the developmental suppression of Th17 and Th1 in peripheral lymphoid tissue of anti–IL-9 mAb-treated mice, the frequency of Foxp3+ cells was also slightly diminished at priming stage. At the same time, the effect of IL-9 blockade against the proliferation of MOG35–55 peptide-specific periphery T cells suggests that the deficiency of CNS-infiltrating CD4+ T cells in anti–IL-9 mAb-treated mice was perhaps due to a T cell priming defect. However, at the peak stage, Foxp3 mRNA increased in the CNS. The reason for the preferential accumulation of regulatory T cells in the CNS under anti–IL-9 mAb treatment should be further investigated.

In conclusion, our studies suggest that the protective effect of anti–IL-9 mAb treatment in EAE is mediated not only via suppression of IL-9–induced inflammatory reactions, but also via inhibition of the induction of MOG35–55 peptide-specific Th17 and
Th1 cells, which in turn leads to reduced infiltration of T cells into the CNS. These findings not only provide evidence for an important pathogenic role of IL-9 in EAE, but also indicate that anti-IL-9 mAb treatment might represent a promising therapy for human MS and other Th17-mediated chronic autoimmune diseases.
