Indirect Stimulation of Human Vγ2Vδ2 T Cells through Alterations in Isoprenoid Metabolism

Hong Wang,* Ghanashyam Sarikonda,*1 Kia-Joo Puan,*2 Yoshimasu Tanaka,† Ju Feng,‡ José-Luis Giner,§ Rong Cao,§ Jukka Mönkkönen,¶ Eric Oldfield,¶ and Craig T. Morita*†

Human Vγ2Vδ2 T cells monitor isoprenoid metabolism by recognizing (E)-4-hydroxy-3-methyl-but-2-enyl pyrophosphate (HMBPP), an intermediate in the 2-C-methyl-d-erythritol-4-phosphate pathway used by microbes, and isopentenyl pyrophosphate (IPP), an intermediate in the mevalonate pathway used by humans. Aminobisphosphonates and alkylamines indirectly stimulate Vγ2Vδ2 cells by inhibiting farnesyl diphosphate synthase (FDPS) in the mevalonate pathway, thereby increasing IPP/triphosphoric acid 1-adenosin-5’-yl ester 3-(3-methylbut-3-etyl) ester that directly stimulate. In this study, we further characterize stimulation by these compounds and define pathways used by new classes of compounds. Consistent with FDPS inhibition, stimulation of Vγ2Vδ2 cells by aminobisphosphonates and alkylamines was much more sensitive to statin inhibition than stimulation by prenyl pyrophosphates; however, the continuous presence of aminobisphosphonates was toxic for T cells and blocked their proliferation. Aminobisphosphonate stimulation was rapid and prolonged, independent of known Ag-presenting molecules, and resistant to fixation. New classes of stimulatory compounds—mevalonate, the alcohol of HMBPP, and alkenyl phosphonates—likely stimulate Vγ2Vδ2 T cells and that pulsing aminobisphosphonates would be more effective for the ex vivo expansion of Vγ2Vδ2 T cells for adaptive cancer immunotherapy. The Journal of Immunology, 2011, 187: 5099–5113.

Human γδ T cells expressing the Vγ2Vδ2 TCR (also termed Vγ9Vδ2) recognize both exogenous prenyl pyrophosphates (also termed prenyl diphosphates) from bacteria and parasitic protozoa, as well as endogenous prenyl pyrophosphates from the mevalonate pathway (1). This recognition is important for the control of infections (2, 3) and for tumor immunotherapy (4–8). In this sense, γδ T cells function as a bridge between the innate and adaptive immune systems, by monitoring intermediates in isoprenoid metabolism (9).

There have been three major classes of nonpeptide compounds described that stimulate Vγ2Vδ2 T cells: prenyl pyrophosphates (10, 11), aminobisphosphonates (12, 13), and alkylamines (14). Prenyl pyrophosphates and alkylamines are natural Ags that can be produced by bacteria and other human pathogens during infections. Aminobisphosphonates are synthetic compounds that mimic prenyl pyrophosphates and are used to treat bone diseases such as osteoporosis (15), Paget’s disease (16), and metastatic tumors in bone (17, 18). Like prenyl pyrophosphates and alkylamines, aminobisphosphonate recognition is mediated by the Vγ2Vδ2 TCR (19), requires Ag presentation by species-specific APCs (20), and is enhanced by costimulatory molecules (20, 21).

Once stimulated, Vγ2Vδ2 T cells secrete high levels of inflammatory cytokines and chemokines, such as IFN-γ and TNF-α (22), and kill tumor cells (4, 23).

Although aminobisphosphonates are structural analogs of prenyl pyrophosphates, the mechanism by which aminobisphosphonates stimulate γδ T cells differs from that of prenyl pyrophosphates. Although the exact molecular mechanisms are unclear, prenyl pyrophosphates are directly presented by APCs for Vγ2Vδ2 TCR recognition primarily by germline-encoded regions (24), leading...
to T cell activation (25). In contrast, aminobisphosphonates appear to stimulate VγVδ2 T cells through an indirect mechanism by inhibiting farnesyl diphosphate synthase (FDPSS), thereby increasing the level of the upstream metabolite isopentenyl pyrophosphate (IPP) (Fig. 1). In support of this mechanism, increases in 3-hydroxy-3-methylglutaryl-Coenzyme A reductase (HMGR, also termed HMG-CoA reductase) activity, the rate-limiting step in IPP synthesis, increase the stimulatory ability of tumor cells in a manner similar to treatment with aminobisphosphonates (26). Moreover, statins that inhibit the HMGR enzyme also inhibit aminobisphosphonate and alkylamine stimulation of VγVδ2 T cells (26–28).

Although the basic mechanisms for indirect stimulation of VγVδ2 T cells by aminobisphosphonates and alkylamines have been established, many questions remain. For example, why are they unable to stimulate proliferative response by VγVδ2 T cell clones (21)? How quickly do bisphosphonates render APCs stimulatory? How specific is statin inhibition of aminobisphosphonate responses, given reports that statins also alter the responses of αβ T cells and other cells of the immune system (29–31)? Moreover, besides direct stimulators such as prenyl pyrophosphates and other ester-linked carbon-phosphate analogs (32, 33), how do other novel compounds, such as mevalonate (27), the alcohol of HMBPP (34), alkenyl-pyrophosphates, and alkyl-bisphosphonates, stimulate VγVδ2 T cells? And finally, are there enzymes other than FDPS whose inhibition will stimulate VγVδ2 T cells?

To address these questions, we examined in detail how bisphosphonates and alkylamines, as well as other novel classes of compounds, stimulate VγVδ2 T cells. We found that stimulation of VγVδ2 T cells by aminobisphosphonates and alkylamines is more sensitive to statin inhibition than other compounds that either activate directly or use other indirect pathways, and that there are additional pathways for the stimulation of human VγVδ2 T cells, through alterations in isoprenoid metabolism.

Materials and Methods

Compounds

Synthesis of bisphosphonates was performed as described previously (13, 35, 36). Prior to use, 20 mM stock solutions were prepared by dissolving the compounds in ultrapureified dH2O, adjusting the pH to 7.0 as required, and filtering through a 0.22 μm Spin-X mini-filter (Corning, Lowell, MA). (E)-4-hydroxy-3-methyl-but-2-ethyl pyrophosphate (HMBPP) was prepared as described (37). Bromohydryl pyrophosphate (3-bromo-3-hydroxybutyl pyrophosphate; BrHPP) was prepared as described (38). Crude monoethylpyrophosphate was prepared as described (10). Triphosphoric acid 1-adenosyl-5′-yl ester 3-(3-methylbut-3-enyl) ester (ApppI) was prepared as described (11). Tetanus toxoid was obtained from the University of Massachusetts Biologic Laboratories (Jamaica Plain, MA).

Derivation and culture of T cell clones

T cell lines and clones were maintained by periodic restimulation with PHA as previously described (39). The derivation of the CD8αα T cell clone (12G12) and the weakly cytotoxic CD4+ γδ T cell clones (HF.2, JN.23, and JN.24) have been described (10, 40, 41). Tetanus toxoid used in the experiments was obtained from J. Gardner (National Institutes of Health, Bethesda, Maryland). APCs were prepared from splenocytes of C57BL/6 mice by Ficoll-Hypaque density centrifugation. PBMCs (1–3 × 107 cells/ml) in Dulbecco’s PBS without calcium or magnesium were incubated with fresh mitomycin C (Sigma-Aldrich, St Louis, MO) at 100 μg/ml for 1 h at 37°C in a 5% CO2 incubator, washed three times in PBS, and resuspended in either supplemented RPMI 1640 media ( termed P-media (44) or PBS for use. For glutaraldehyde fixation, APCs were adjusted to 1–3 × 106 cells/ml in PBS and reacted with 0.05% glutaraldehyde (EM grade; Sigma-Aldrich) for 15 s at room temperature with gentle vortexing. The reaction was stopped by adding an equal volume of 0.2 M L-lysine (in H2O at pH 7.4) and incubating for 2 min. The fixed cells were then washed three times in PBS and resuspended in either P-media or PBS for use. For Ag pulsing, mitomycin C-treated or glutaraldehyde-fixed APCs were plated in round-bottom 96-well plates (Corning) at 1 × 105 cells well in PBS and incubated with the compound indicated at 37°C for 1 h. The cells were then washed three times with PBS and resuspended in P-media for mixing with T cells. For statin inhibition experiments, VγVδ2 T cell responses were generally adjusted such that they were at least 45% of the maximum response. Pravastatin stock solution was made directly with water; mevastatin and simvastatin were first dissolved in 100% ethanol, and an equal volume of water was added to make stock solutions. All statins were obtained from Calbiochem and were the (active) sodium carbonate salts. For statin inhibition, APCs were preincubated with the statin for 3 h. For pulsing, APCs were cultured with stimulatory compounds in the presence of the statin and then washed. T cells were then added with the statin so that the statin was present during for the entire duration of culture. Similarly, APCs were preincubated with cell transport inhibitors (chloroquine, ammonium chloride, bafilomycin A1, brefeldin A, monensin, wortmannin, cytochalasin D, and nocodazole; Sigma-Aldrich) for 30 min, followed by either pulsing with stimulatory compounds for 60 min or continuously culturing with stimulatory compounds, in the presence of the inhibitors. T cells were then added in the presence of the inhibitors.

T cell proliferation and cytokine release

T cell proliferation assays were performed as described previously (45). Assays were in duplicate or triplicate in round-bottom 96-well plates using 1 × 106 T cells well in the presence of nonfixed (mitomycin C-treated) or fixed APCs at 1 × 105 cells per well for Ag and PHA stimulation, or in the absence of APCs for IL-2 stimulation. Stimulating compounds and inhibitors were used as indicated in the figure legends. For T cell responses, culture supernatants were harvested after 16 h and assayed for TNF-α or IFN-γ levels by DuoSet sandwich ELISA (R&D Systems, Minneapolis, MN). A standard curve was derived from serial dilution of each cytokine standard, and used to calculate the cytokine concentration in picograms per milliliter. Mean cytokine levels and SEM of duplicate or triplicate cultures are shown.

In vitro expansion of VγVδ2 T cells

For in vitro expansion of blood VγVδ2 T cells by bisphosphonates, PBMCs were prepared from the blood or leukopaks of normal donors by Ficoll-Hypaque density centrifugation. PBMCs (1 × 106) in 0.2 ml media in 96-well round-bottom wells were seeded with the compounds for 2–6 h, washed twice, or cultured continuously with the compounds. IL-2 containing media was added on day 3. The cells were harvested on day 9, stained with the HITA3 FITC–anti-CD3 (eBioscience) and B6 PE-anti-VγVδ (BD Pharmingen) monoclonal Abs, and analyzed using flow cytometry.

Measurement of calcium flux by flow cytometry

Calcium flux was measured using a flow cytometric assay with indo-1 (Invitrogen, Molecular Probes, Eugene, OR) as described previously (25). Indo-1–loaded T cells (without APCs) were incubated at 37°C for 2 min and analyzed for 30 s to establish baseline levels, and then Ag was added. For samples that were not spun, cells were analyzed for an additional 3 min. For spun samples, cells were analyzed for an additional 30 s to establish baseline calcium levels after Ag addition. The T cells were then centrifuged for 20 s in a microcentrifuge to initiate cell–cell contact and incubated for an additional 50 s at 37°C. The cells were resuspended, introduced into the flow cytometer, and analyzed for an additional 2–3 min. The mean ratios of indo-1 fluorescence at 405/485 nm are shown.

Measurement of intracellular IPP levels

Cells were treated with various compounds or small interfering RNA (siRNA), harvested from culture, washed twice with PBS, counted, and spun down. Ice-cold acetonitrile (300 μl) was then added to the cell pellet to precipitate macromolecules, followed by the addition of 200 μl water. The precipitate was removed by centrifugation (13,000 × g for 3 min), and the supernatant was transferred immediately to a new tube. The cell extracts were then evaporated in vacuo and stored at −80°C until use. For liquid chromatography/mass spectrometry (LC/MS) determination of IPP levels of siRNA-treated APCs, samples were dissolved in 50 μl of 12 mM

Downloaded from http://www.jimmunol.org/ by guest on April 11, 2017
ammonium formate. Metabolites were separated by reverse-phase HPLC using a ZORBAX Eclipse XDB-C8 column (Agilent Technologies) and analyzed by positive ion electrospray mass spectrometry using an MSQ Trap XCT Plus spectrometer (Agilent Technologies) as described (36). For LC/MS determination of IPP and Appi in APCs incubated with different compounds, MCF-7 cells were incubated with the various compounds and cell extracts were prepared as above. Levels of IPP and Appi were determined by separation of metabolites on high-performance, ion-pairing, reverse-phase liquid chromatography using a Gemini C18 column (Phenomenex) with N,N-dimethylhexylamine formate as the ion pairing agent and analysis by negative-ion electrospray ionization mass spectrometry as described (46).

**siRNA transfection and real-time PCR**

For each enzyme, three different siRNAs were purchased from Invitrogen. Enzymes targeted were isopentenyl diphosphate isomerase (IDI), FDPS, geranylgeranyl diphosphate synthase (GGPS), squalene synthase (SQS) (also termed farnesyl-diphosphate farnesyltransferase 1), dehydrodolichol diphosphate synthase (DHDSS), and prenyl (decaprenyl) diphosphate synthase subunit 2 (PDSS2). Note that diphosphate is also termed pyrophosphate. For transfection, HeLa cells were plated at 2 × 10^5 cells per well in 6-well plates 1 d before use. For transfection, 12 μl HiPerFect transfection reagent (Qiagen, Germantown, MD) was added to 150 ng siRNA diluted in 100 μl serum-free OPTI-MEM I (Invitrogen). After vortexing for 10 s and incubating at room temperature for 5–10 min, the transfection complexes were added drop-wise onto the cells in each well. The transfected cells were then incubated at 37˚C and 10% CO_2 for the transfection complexes were added drop-wise onto the cells in each well. After vortexing for 10 s and incubating at room temperature for 5–10 min, the transfection complexes were added drop-wise onto the cells in each well. The transfected cells were then incubated at 37˚C and 10% CO_2 for 24–96 h before harvesting for future use. For mRNA detection, siRNA transfection and real-time PCR

**Stimulation of DBS43 Vγ2Vδ2 TCR transfectant**

Derivation of the DBS43 Vγ2Vδ2 TCR transfectant is described (47). Stimulation of TCR transfectants for IL-2 release was performed as described (47, 48). Briefly, 1 × 10^5 transfectants or the parent J.RT3-T3.5 cells were cultured with anti-TCRαβ mAb concentrated culture supernatant, HMBPP, ionomycin, or siRNA-treated HeLa tumor cells in the presence of 1 × 10^5 glutaraldehyde-fixed Va-2 cells (except for tumor cells) and 10 ng/ml PMA. After 24 h, supernatants were harvested and frozen at –20˚C. For IL-2 assays, the supernatants were thawed and used at a 1:8 dilution to stimulate the proliferation of the IL-2-dependent cell line, HT-2. The cultures were pulsed with 1 μCi of [3H]-thymidine (2 Ci/mmol) at 18 h and harvested 6 h later.

**Results**

Aminobisphosphonates can be pulsed into APCs to reduce their nonspecific inhibition of T cell proliferation

Aminobisphosphonates stimulate Vγ2Vδ2 T cells by inhibiting FDPS, leading to the accumulation of IPP (Fig. 1). Previous experiments on aminobisphosphonate stimulation of Vγ2Vδ2 T cell clones and lines have focused on cytokine release (26), because the cells did not proliferate (21). Confirming these studies, the JN.23 Vγ2Vδ2 T cell clone released TNF-α in response to the aminobisphosphonate, risedronate (Fig. 2A), and to the prenyl pyrophosphate analog, monoethyl-pyrophosphate (Supplemental Fig. 1A). Whereas Vγ2Vδ2 T cells proliferated with exposure to monoethyl pyrophosphate (with a slight response even in the absence of APC), there was little proliferation with exposure to risedronate, either in the absence or presence of APCs (Fig. 2A).

We showed previously that glutaraldehyde fixation increases constitulatory and accessory functions of APCs for Vγ2Vδ2 T cells (45). When glutaraldehyde-fixed APCs were used, Vγ2Vδ2 T cell proliferation was observed with risedronate, but only in a narrow dose range, with responses observed at 10-fold lower concentrations than TNF-α release in the presence of nonfixed APCs (Fig. 2A). This lack of Vγ2Vδ2 T cell proliferation was not

![FIGURE 1. Mevalonate pathway and key downstream branches in isoprenoid biosynthesis. 3-hydroxy-3-methylglutaryl-Coenzyme A reductase is the rate-controlling enzyme in the mevalonate pathway and is subject to feedback regulation by downstream products. It is also inhibited by statins. Farnesyl pyrophosphate (FPP) synthase converts IPP and DMAPP to geranyl pyrophosphate and FPP intermediates and is inhibited by aminobisphosphonates and alkylaminals. Loss of FPP and geranylgeranyl pyrophosphate leads to the loss of membrane anchoring of signaling proteins, causing signaling defects and, in some cases, apoptosis.](http://www.jimmunol.org/Downloaded From http://www.jimmunol.org/)
observed when APCs were pulsed with risedronate, because both nonfixed and fixed APCs pulsed with risedronate induced strong proliferative responses (Fig. 2B). Similar results were noted with other aminobisphosphonates (Supplemental Fig. 2). These results suggest that continuous exposure to risedronate blocks Vγ2Vδ2 T cell proliferation unless highly effective APCs are used.

Toxicity was also noted when various aminobisphosphonates were used continuously to expand Vγ2Vδ2 T cells from PBMCs, with variable maximal expansions and narrow dose response ranges (Fig. 2C). In contrast, when aminobisphosphonate exposure was limited to 4 h, blood Vγ2Vδ2 T cells expanded to similar maximal levels for both conventional (zoledronate), pyridinium (bisphosphonate [BPH]-278 and BPH-300), and lipophilic (BPH-777) aminobisphosphonates with broad peak responses over a 10- to 30-fold range (Fig. 2D). Exposure of Vγ2Vδ2 T cells to 100 μM zoledronate for 8 h reduced expansion by 50%, whereas exposure for 6 h or less had a minimal effect (Fig. 2E).

To determine whether this loss of proliferation was specific for Vγ2Vδ2 T cells, the effect of aminobisphosphonates on IL-2–induced and mitogen-induced proliferation of Vγ1Vδ1, Vγ2Vδ1, and αβ T cell clones was tested. All T cell proliferative responses were inhibited by risedronate (inhibitory concentration reducing responses by 50% [IC50] ranged from 50–1000 μM; Supplemental Fig. 1B). Thus, aminobisphosphonate inhibition of FDPS within APCs blocks isoprenoid metabolism, resulting in IPP accumulation. This block also can cause nonspecific inhibition of T cell proliferation at higher concentrations.

Aminobisphosphonates rapidly stimulate Vγ2Vδ2 T cells in an MHC-independent manner

To determine how rapidly aminobisphosphonates make APCs stimulatory for Vγ2Vδ2 T cells, calcium flux responses of Vγ2Vδ2 T cells to risedronate were compared with response to HMBPP. When in cell–cell contact, aminobisphosphonates stimulated calcium flux in Vγ2Vδ2 T cells within 2 min, with similar kinetics as HMBPP (Fig. 3A). Risedronate had no effect on Vγ1Vδ1 T cells (Fig. 3A, right bottom panel), and without cell–cell contact no responses were observed (Fig. 3A, left panel). Consistent with the

---

**FIGURE 2.** Aminobisphosphonate toxicity for Vγ2Vδ2 T cell can be avoided by pulsing. A, Continuous culture of Vγ2Vδ2 T cells with aminobisphosphonates inhibits their proliferation, but not TNF-α release. Mitomycin C-treated or glutaraldehyde-fixed CPEBV cells were continuously cultured with risedronate and the CD4+ Vγ2Vδ2 T cell clone, JN.23. Supernatants were collected at 16 h for the measurement of TNF-α. The cells were pulsed with [3H]-thymidine and harvested 18 h later. B, APCs pulsed with risedronate stimulate both proliferation and TNF-α release. Risedronate was pulsed into APCs, washed, and mixed with the CD4+ Vγ2Vδ2 T cell clone, JN.23. TNF-α and cell proliferation were measured as in A. C, Variable expansion of blood Vγ2Vδ2 T cells with continuous exposure to aminobisphosphonates. PBMCs were cultured with various aminobisphosphonates for 10 d, and Vγ2Vδ2 T cells and CD3+ T cells were determined by flow cytometry. D, Consistent blood Vγ2Vδ2 T cell responses to aminobisphosphonates pulsed into monocytes. PBMCs were pulsed for 4 h with the various aminobisphosphonates. The PBMCs were then washed and cultured in the presence of IL-2. After 9 d, Vγ2Vδ2 T cells and CD3+ T cells were determined by flow cytometry. E, Expansion of blood Vγ2Vδ2 T cells in PBMCs pulsed with zoledronate. PBMCs were pulsed for the indicated time with zoledronate, washed, and cultured in the presence of IL-2. After 9 d, Vγ2Vδ2 T cells and CD3+ T cells were determined by flow cytometry.
rapid calcium flux, APC exposure to risedronate for as short as 5 min rendered the APCs stimulatory for Vγ2Vδ2 T cells similar to pulsing with HMBPP (Supplemental Fig. 3A). Prolonged risedronate exposure for 120 min only increased EC50 3-fold compared with APCs pulsed for 5 min. Thus, risedronate stimulation is rapid and dependent on cell–cell contact.

Because aminobisphosphonates are proposed to function intra-cellularly, fixation of APCs could disrupt uptake. However, when APCs were fixed and then pulsed with risedronate, no significant reduction in Vγ2Vδ2 T cell stimulation was observed (Fig. 3B). APC fixation was judged adequate because APC fixation before pulsing, but not after, inhibited the response of the SP-F3 CD4 αβ T cell clone to tetanus toxoid, indicating sufficient APC fixation to abolish the presentation of a protein Ag by MHC class II HLA-DR. In contrast, APC fixation before or after risedronate pulsing had no effect on Vγ2Vδ2 T cell responses (Fig. 3B), demonstrating that aminobisphosphonate stimulation is resistant to glutaraldehyde fixation.

We next determined how long APCs pulsed with aminobisphosphonates remain stimulatory for Vγ2Vδ2 T cells. APCs pulsed with aminobisphosphonates stimulated Vγ2Vδ2 T cells for up to 24 h, whereas APCs pulsed with HMBPP lost their ability to stimulate by 4 h (Fig. 3C). APC fixation did not affect the retention of aminobisphosphonate activity, because both nonfixed
and fixed APCs lost their ability to stimulate with the same kinetics (Fig. 3C).

The ability of aminobisphosphonates to pulse into APCs allowed us to determine the requirement for known Ag-presenting molecules under conditions where self presentation of Ags was not possible. Expression of MHC class I (HLA-A, -B, and -C), MHC class II, β2-microglobulin, and CD1a, CD1b, CD1c, and CD1d (absent on CP.EBV, 721, and 721.221) was not required, because APCs lacking these molecules stimulated Vγ2Vδ2 T cells when pulsed with risedronate (Fig. 3D). In addition, like prenyl pyrophosphates and contrary to a report using the stimulatory Daudi cell line as the APC (26), stimulation by aminobisphosphonates using a conventional B cell line was not greatly affected by low temperature or monensin (Supplemental Fig. 3B, 3C). However, monensin treatment did abolish the intrinsic stimulatory activity of Daudi (Supplemental Fig. 3B). There was moderate inhibition by other cellular inhibitors (chloroquine, ammonium chloride, bafilomycin A1, brefeldin A, Wortmannin, cytochalasin D, and nocodazole), but none blocked completely (data not shown).

Aminobisphosphonate-stimulated Vγ2Vδ2 T cell responses are more sensitive to statin inhibition than responses induced by prenyl pyrophosphates and superantigens

Statins inhibit HMGCR, the rate-limiting enzyme in the mevalonate pathway that is upstream from FDPS (Fig. 1). Statins are reported to specifically inhibit Vγ2Vδ2 T cell responses to aminobisphosphonates (26, 27) and alkylamines (28). However, they are also reported to alter αβ T cell responses as well as the functions of other cells of the immune system (29–31). To reconcile these apparent differences, we investigated the effect of statins on Vγ2Vδ2 T cell responses in more detail.

We first determined the relationship between the magnitude of the Vγ2Vδ2 T cell response to risedronate and its sensitivity to statin inhibition. Risedronate responses between 50 and 100% of the maximum response were inhibited by mevastatin at concentration varying only between 1 and 3 μM (Supplemental Fig. 4A). In contrast, when risedronate responses were weaker (<50% of maximum), sensitivity to statin inhibition increased 10– to 100-fold (IC50 values between 0.013 and 0.01 μM; Supplemental Fig. 4A, 4B). Much of the aminobisphosphonate response could be restored by mevalonate (the product of the HMGCR enzyme; Supplemental Fig. 4C). Thus, to accurately assess statin sensitivity, the magnitude of the Vγ2Vδ2 T cell response must be considered because sensitivity to statin inhibition increases greatly for responses less than 45% of maximum.

Taking this into consideration, we assessed the sensitivity of different Vγ2Vδ2 T cell stimulators to statin inhibition. Staphylococcal enterotoxin A (SEA) is a superantigen that activates Vγ2^+ T cells through direct presentation by MHC class II (45). Despite a weak response to SEA (3% of the HMBPP maximum), the response to SEA was relatively resistant to mevastatin inhibition (IC50 = 100 μM), requiring a concentration similar to that needed to inhibit the response to HMBPP (IC50 = 63 μM; Fig. 4A). In contrast, risedronate was 333-fold more sensitive to mevastatin inhibition (IC50 = 0.3 μM; Fig. 4A). Two additional statins, pravastatin (lower potency) and simvastatin (higher potency), also preferentially inhibited risedronate responses compared with HMBPP and PHA responses (Fig. 4B). The differences in concentration were ∼10-fold for pravastatin, 30–48-fold for mevastatin, and 76–154-fold for simvastatin (Fig. 4B). Finally, statin treatment of APCs pulsed with both risedronate and tetanus toxoid showed that risedronate-induced Vγ2Vδ2 T cell responses were 38-fold more sensitive to mevastatin inhibition than tetanus toxoid-induced αβ T cell responses presented by the same APCs (Fig. 4C).

Because these experiments used a CD4^+ Vγ2Vδ2 T cell clone, we evaluated two non-CD4 Vγ2Vδ2 T cell clones to determine whether sensitivity to statin inhibition varied. Mevastatin inhibition was determined for proliferative and TNF-α responses to prenyl pyrophosphates (IPP, HMBPP, and BrHPP) and to aminobisphosphonates (risedronate and alendronate; Fig. 4D). Aminobisphosphonate-induced TNF-α responses were more sensitive to mevastatin inhibition than were prenyl pyrophosphate-induced TNF-α responses for all three clones. In contrast, for proliferative responses only the CD4^+ T cell clone exhibited this increased sensitivity to statin inhibition of aminobisphosphonate responses. No difference in inhibition sensitivity was noted for the CD8α^+ and CD4^+ T cell clones. This pattern was confirmed using additional CD4^+ Vγ2Vδ2 T cell clones (Fig. 4E). We next stimulated freshly isolated blood Vγ2Vδ2 T cells to determine their sensitivity to statin inhibition (Fig. 4F). Zoledronate-induced expansion of blood Vγ2Vδ2 T cells was 80-fold more sensitive to mevastatin inhibition than HMBPP-induced expansion (IC50 = 0.1 versus 8 μM). Thus, the pattern of statin inhibition of blood Vγ2Vδ2 T cells (largely CD8α^+ or CD4^+8^−) was similar to that of CD4^+ Vγ2Vδ2 T cell clones.

High statin concentrations (similar to those inhibiting prenyl pyrophosphate and SEA responses) also inhibited Vγ2Vδ2 T cell, non-Vγ2Vδ2 γδ T cell, and αβ T cell proliferative responses to IL-2 (Supplemental Fig. 4D) and both proliferative and TNF-α responses to the mitogen, PHA (Supplemental Fig. 4E). Statin effects were not due to reductions in APC numbers because APC numbers did not vary with treatment (data not shown). In summary, statins preferentially inhibit the aminobisphosphonate-stimulated proliferation of blood Vγ2Vδ2 T cells and CD4^+ Vγ2Vδ2 T cell clones, but not CD8α^+/CD4^+8^− Vγ2Vδ2 T cell clones. Statins also preferentially inhibit TNF-α release to aminobisphosphonates for all Vγ2Vδ2 T cells. At high doses, statins non-specifically inhibit T cell responses. Therefore, the sensitivity to statin inhibition can distinguish indirect stimulation of Vγ2Vδ2 T cells from direct recognition of Ags by Vγ2Vδ2 T cells.

Statin inhibition distinguishes indirect stimulation because of FDPs inhibition from other pathways for stimulation of Vγ2Vδ2 T cells

Because sensitivity to statin inhibition distinguishes indirect stimulation by aminobisphosphonates from direct recognition of prenyl pyrophosphates and superantigens, statin inhibition can help to distinguish between different pathways for stimulation of Vγ2Vδ2 T cells. Additional classes of compounds have been shown to stimulate Vγ2Vδ2 T cells. Alkylamines are natural products present in some foods, and produced by certain bacteria, that stimulate Vγ2Vδ2 T cells in vitro (14) and prime Vγ2Vδ2 T cells in vivo for increased responsiveness to prenyl pyrophosphates (49). The alcohol of HMBPP, (E)-2-methyl-but-2-ene-1,4-diol (HMB-OBH), stimulates the expansion of Vγ2Vδ2 T cells (34), despite lacking the phosphate groups that are normally essential for the activity of prenyl pyrophosphates. Finally, mevalonate by itself also stimulates the expansion of Vγ2Vδ2 T cells (27).

Consistent with these reports, these compounds stimulated both proliferation and TNF-α release by Vγ2Vδ2 T cells. Whereas HMBPP and risedronate rendered APCs strongly stimulatory after pulsing, HMB-OBH and mevalonate rendered APCs only weakly stimulatory (Fig. 5A). The alkylamine, sec-butylamine, had no effect with pulsing of either nonfixed or fixed APCs (data not shown), but could stimulate Vγ2Vδ2 T cells when present continuously (Fig. 5B). Vγ2Vδ2 T cell responses to these compounds were then tested for their sensitivity to statin inhibition when the compounds were either pulsed with the APCs or
continuously cultured with the APCs and T cells. Whereas Vγ2Vδ2 T cell responses to PHA and HMBPP were relatively resistant to inhibition by mevastatin (Fig. 6A, top 2 rows) and completely resistant to inhibition by pravastatin (data not shown), responses to risedronate were highly sensitive to statin inhibition when the compounds were either pulsed or continuously present (Fig. 6A, bottom row). Similarly, Vγ2Vδ2 T cell responses to sec-butylamine was highly sensitive to statin inhibition, consistent with a report that alkylamines inhibit FDPS activity in cells (28). Finally, like HMBPP and PHA, Vγ2Vδ2 T cell responses to HMB-OH and mevalonate were relatively resistant to statin inhibition when the compounds were either continuously present or pulsed (for HMB-OH; Fig. 6A, third and fourth rows). Thus, the activities of HMB-OH and mevalonate do not appear dependent on FDPS inhibition. To confirm this finding, the levels of intracellular IPP and its metabolite ApppI were measured after incubation of MCF-7 cells with the various stimulators. Whereas zoledronate treatment greatly increased IPP and ApppI levels, IPP was still undetectable after HMBPP, HMB-OH, or mevalonate treatment (Fig. 6B).
A recent report detailed extracellular IPP produced by cells treated with zoledronate (50). HMB-OH could similarly enter cells, become phosphorylated to HMBPP, and then be secreted for presentation to Vγ2Vδ2 T cells. To rule out this mechanism of action, alkaline phosphatase was added to the cultures to hydrolyze extracellular HMBPP. The addition of alkaline phosphatase completely abrogated stimulation by HMBPP but had no effect on HMB-OH stimulation of Vγ2Vδ2 T cells (Fig. 6C), showing that extracellular HMBPP was not responsible for stimulation by HMB-OH. In addition, lysates from HMB-OH–treated cells did not contain HMBPP bioactivity upon HPLC separation (data not shown).

One property of directly presented prenyl pyrophosphates is their ability to stimulate Vγ2Vδ2 T cells in the absence of APCs because of daughter-daughter T cell presentation (25). In contrast, stimulation by ApppI is minimal in the absence of APCs because APCs are required to provide nucleotide phosphorylase to release IPP (51). Because our findings suggested that HMB-OH might be directly presented, the requirement for APCs was tested. Whereas ApppI stimulation was suboptimal in the absence of APCs (Fig. 7A, 7B), HMB-OH stimulated Vγ2Vδ2 T cells in the absence of APCs with kinetics identical to HMBPP and IPP; this was especially evident for TNF-α release (Fig. 7B). Finally, despite lacking phosphates, HMB-OH (EC50% of 3.2 μM) stimulates Vγ2Vδ2 T cells at similar concentrations as the HMB phosphonate analogs, (E)-(hydroxy(5-hydroxy-4-methyl-pent-3-enyl)phosphoryl)methyl-phosphonate (HMB-CPCP; EC50% of 4.6 μM) and (E)-1-hydroxy-2-methyl-but-2-enyl 4-(methylene-diphosphonate) (HMB-OPCP; EC50% of 5.5 μM; 34). HMB-OH does not inhibit FDPS, but appears to stimulate Vγ2Vδ2 T cells directly.

Alkenyl-pyrophosphonates and alkyl-bisphosphonates directly stimulate Vγ2Vδ2 T cells

Other classes of phosphonate compounds that stimulate Vγ2Vδ2 T cells include alkenyl pyrophosphonates containing -CPOP moieties (52, 53), alkenyl-methylene diposphonates (-OPCP), and alkenyl-phosphorylmethylphosphonates (-CPCP). These compounds can either stimulate Vγ2Vδ2 T cells (e.g., HMB-OPCP) (34, 54) or antagonize prenyl pyrophosphate responses (e.g., bromohydrin methylene-diphosphate [BrH-OPCP]) (44, 55). To assess the mechanism of action of these compounds, we compared statin inhibition of the response to HMB-CPCP with that of HMBPP and risedronate. As expected, HMBPP was relatively resistant to statin inhibition, whereas risedronate was highly sensitive. Consistent with direct recognition, HMB-CPCP required high statin concentrations for inhibition that were identical to those required by

FIGURE 5. Multiple compounds stimulate Vγ2Vδ2 T cells. A, Stimulation of Vγ2Vδ2 T cells by HMBPP, HMB-OH, mevalonate, and risedronate. The JN.24 Vγ2Vδ2 T cell clone was cultured with nonfixed (mitomycin C-treated) or fixed Va2 APCs that had been pulsed with the indicated compounds, or the compounds were added continuously. T cell proliferation and TNF-α release were measured as described in Fig. 2A. B, Stimulation of Vγ2Vδ2 T cells by sec-butyramine and risedronate. Untreated CP.EBV and the HF.2 Vγ2Vδ2 T cell clone were cultured continuously with either risedronate or sec-butylamine. Supernatants were collected 16 h later for determination of TNF-α.
HMBPP (Fig. 8A). Given the structural similarities, alkenyl-pyrophosphonates, alkenyl-methylene diphosphonates, and alkenyl-phosphorylmethylphosphonates directly stimulate V\(\gamma\)2\(\delta\)T cells.

In our testing of different bisphosphonates, we found a new class of compounds—alkyl-bisphosphonates—that stimulate V\(\gamma\)2\(\delta\)T cells (Fig. 8B). These compounds have identical alkyl-1,1-bisphosphonate structures as aminobisphosphonates, but lack amino moieties and thus have similarities also to alkyl-pyrophosphates (10, 32). Alkyl-bisphosphonates stimulate V\(\gamma\)2\(\delta\)T cells with EC\(\text{50}\) of ∼300–700 \(\mu\)M (Fig. 8B). To determine the effect of the loss of the amino moiety on the mechanism of action for V\(\gamma\)2\(\delta\)T cell stimulation, the sensitivity to statin inhibition of the V\(\gamma\)2\(\delta\)T cell response to an alkyl-bisphosphonate (1-hydroxy-butane-1,1-bisphosphonate) was compared with an alkyl-pyrophosphate (\(n\)-propyl-pyrophosphate) and the aminobisphosphonate, pamidronate (3-amino-1-hydroxy-propane-1,1-bisphosphonate). As expected, the V\(\gamma\)2\(\delta\)T cell response to the aminobisphosphonate pamidronate was highly sensitive to mevastatin inhibition (IC\(\text{50}\) = 0.04 \(\mu\)M; Fig. 8C). Surprisingly, the loss of the amino group in 1-hydroxy-butane-1,1-bisphosphonate increased the resistance to statin inhibition 175-fold (IC\(\text{50}\) = 7 \(\mu\)M) to concentrations similar to those required to inhibit n-propyl-pyrophosphate responses (IC\(\text{50}\) = 10 \(\mu\)M; Fig. 8C). We hypothesize that the loss of the amino moiety switches aminobisphosphonates from indirect stimulators to direct stimulators. Thus, the amino moiety of bisphosphonates has a key role in determining their mechanism of action for stimulating V\(\gamma\)2\(\delta\)T cells.

siRNA treatment of APCs identifies FDPS and IDI as enzyme targets for the development of V\(\gamma\)2\(\delta\)T cell stimulators

Given that aminobisphosphonates and alkylamines inhibit FDPS to stimulate V\(\gamma\)2\(\delta\)T cells, we sought to determine whether the inhibition of other enzymes involved in isoprenoid biosynthesis might stimulate V\(\gamma\)2\(\delta\)T cells. IPP is required for many isoprenoid biosynthetic reactions, such as the synthesis of geranylgeranyl pyrophosphate and CoQ\(_{10}\). HeLa cells were therefore transfected with siRNAs specific for key downstream enzymes in the isoprenoid pathway, including IDI, FDPS, GGPS, SQS, PDSS2, and DHDDS (Fig. 1). Transfection of siRNAs greatly decreased mRNA levels (most >90%) in all cases tested (Fig. 9A).
Consistent with the proposed mechanism of action of aminobisphosphonates and alkylamines and with experiments using short hairpin RNA for FDPS (56), HeLa cells transfected with siRNA targeting FDPS stimulated V<sup>g</sup><sub>2</sub>V<sup>d</sup><sub>2</sub> T cells (Fig. 9B). HeLa cells transfected with FDPS siRNA began to stimulate V<sup>g</sup><sub>2</sub>V<sup>d</sup><sub>2</sub> T cells by 72 h and peaked at 96 h. The ability of FDPS siRNA transfectants to stimulate V<sup>g</sup><sub>2</sub>V<sup>d</sup><sub>2</sub> T cells correlated with intracellular IPP levels. At 72 h after transfection, when FDPS siRNA transfected-HeLa cells begin to show weak stimulatory activity, their intracellular IPP levels were slightly increased. At 96 h after transfection, when the ability of transfectants to stimulate V<sup>g</sup><sub>2</sub>V<sup>d</sup><sub>2</sub> T cells peaked, IPP level were dramatically elevated (Fig. 9C). Mevastatin preferentially inhibited the V<sup>g</sup><sub>2</sub>V<sup>d</sup><sub>2</sub> T cell response to APCs transfected with siRNA for FDPS with an identical dose response to that of risedronate (Fig. 9D). Finally, recognition of FDPS siRNA-treated cells was mediated by the V<sup>g</sup><sub>2</sub>V<sup>d</sup><sub>2</sub> TCR because Jurkat cells transfected with V<sup>g</sup><sub>2</sub>V<sup>d</sub><sub>2</sub> TCRs (DBS43) released IL-2 in response to FDPS siRNA transfected HeLa cells, whereas these APCs had no effect on the parent cell line (J.RT3-T3.5; Fig. 9E).

siRNA specific for IDI also stimulated V<sup>g</sup><sub>2</sub>V<sup>d</sup><sub>2</sub> T cells. HeLa cells transfected with an siRNA specific for IDI (IDI 195) stimulated moderate levels of V<sup>g</sup><sub>2</sub>V<sup>d</sup><sub>2</sub> T cell proliferation, IFN-γ release, and TNF-α release (Fig. 9F, top panels) that were ~25% of the FDPS stimulation levels (Fig. 9F, bottom panels). Thus, downregulation of either FDPS or IDI renders APCs stimulatory for V<sup>g</sup><sub>2</sub>V<sup>d</sup><sub>2</sub> T cells (Fig. 10, middle), whereas no stimulation of V<sup>g</sup><sub>2</sub>V<sup>d</sub><sub>2</sub> T cells was found with the downregulation of other enzymes.

**Discussion**

This study shows that there are other indirect pathways leading to the stimulation of V<sup>g</sup><sub>2</sub>V<sup>d</sup><sub>2</sub> T cells besides the inhibition of FDPS. Downregulation of IDI stimulates V<sup>g</sup><sub>2</sub>V<sup>d</sub><sub>2</sub> T cells as does exposure to high concentrations of mevalonate (Fig. 10). All are related by the fact that they alter isoprenoid metabolism leading to the increased production of prenyl pyrophosphates that directly activate V<sup>g</sup><sub>2</sub>V<sup>d</sup><sub>2</sub> T cells. These findings suggest that V<sup>g</sup><sub>2</sub>V<sup>d</sup><sub>2</sub> T cells may be involved in surveillance for cancer cells because relatively small increases in IPP levels are recognized. Moreover, prolonged exposure of V<sup>g</sup><sub>2</sub>V<sup>d</sup><sub>2</sub> T cells to higher doses of aminobisphosphonates has the paradoxical effect of inhibiting their ability to proliferate. This is due to their blocking isoprenoid metabolism in the T cells. These findings suggest that aminobisphosphonates should be pulsed to limit toxicity when used for ex vivo expansion of V<sup>g</sup><sub>2</sub>V<sup>d</sup><sub>2</sub> T cells for cancer immunotherapy.
Because IPP is used for the synthesis of many isoprenoid compounds, inhibition of other enzymes besides FDPS might also increase IPP levels sufficiently to stimulate Vγ2Vδ2 T cells. One candidate enzyme, IDI, is upstream of FDPS and its inhibition would be predicted to cause IPP (its substrate) to accumulate (Fig. 1). Consistent with this prediction, we found that treatment of APCs with siRNA targeting IDI made them stimulatory for Vγ2Vδ2 T cells (Fig. 10, middle). This finding suggests that inhibitors of IDI would also stimulate Vγ2Vδ2 T cells. Because an aminobisphosphonate exists that inhibits both IDI and FDPS (57) and stimulates Vγ2Vδ2 T cells (27), it may be possible to design specific bisphosphonate inhibitors of IDI. Given that dimethylallyl pyrophosphate (DMAPP) exhibits 3–30-fold lower bioactivity than IPP (32), such compounds could have increased potency for stimulating Vγ2Vδ2 T cells or different biologic effects compared with FDPS inhibitors, because only IPP will accumulate rather than both IPP and DMAPP that accumulate with FDPS inhibitors. Besides IDI, no effects were seen upon GGPS inhibition using aminobisphosphonates specific for this enzyme (36) or upon APC transfection with siRNAs specific for GGPS, SQS, PDSS2, or DHDDS, suggesting that blocking only one branch of downstream isoprenoid biosynthesis is not sufficient for IPP accumulation and Vγ2Vδ2 stimulation.

Mevalonate also stimulated Vγ2Vδ2 T cells. Because mevalonate is the product of HMGCR, a rate-limiting enzyme subject to tight regulation (58–61), high exogenous mevalonate concentrations would bypass normal regulation and increase the levels of downstream products including IPP and DMAPP (Fig. 1). Statins would be unable to block this stimulation as was observed in this study (Fig. 6A). Because intracellular IPP levels were below detection levels in both normal and mevalonate-treated cells (Fig. 6B), the degree of IPP increase is unclear, but certainly less than those observed with aminobisphosphonate treatment. Because relatively small increases in IPP levels (25% for FDPS siRNA treated cells) stimulated Vγ2Vδ2 T cells (Fig. 9C), there easily could have been sufficient increases in IPP to stimulate γδ T cells. Based on our findings, we propose that mevalonate acts indirectly—stimulating Vγ2Vδ2 T cells by increasing endogenous IPP levels in APCs (Fig. 10, bottom).

Although aminobisphosphonates stimulate Vγ2Vδ2 T cells to release TNF-α, we found that they could also inhibit Vγ2Vδ2 T cell proliferation upon continuous exposure. The blocking of FDPS by aminobisphosphonates results in decreased levels of farnesyl pyrophosphate and geranylgeranyl pyrophosphate. Upon activation of T cells, farnesyl and geranylgeranyl moieties are transferred to the C termini of GTPases, allowing them to anchor in the inner leaflet of the plasma membrane and function in signal transduction. Prolonged exposure to aminobisphosphonates results in decreased levels in APCs (Fig. 10, middle) with narrow dose responses that would be unable to block this stimulation as was observed in this study (Fig. 6A). Because intracellular IPP levels were below detection levels in both normal and mevalonate-treated cells (Fig. 6B), the degree of IPP increase is unclear, but certainly less than those observed with aminobisphosphonate treatment. Because relatively small increases in IPP levels (25% for FDPS siRNA treated cells) stimulated Vγ2Vδ2 T cells (Fig. 9C), there easily could have been sufficient increases in IPP to stimulate γδ T cells. Based on our findings, we propose that mevalonate acts indirectly—stimulating Vγ2Vδ2 T cells by increasing endogenous IPP levels in APCs (Fig. 10, bottom).

Although aminobisphosphonates stimulate Vγ2Vδ2 T cells to release TNF-α, we found that they could also inhibit Vγ2Vδ2 T cell proliferation upon continuous exposure. The blocking of FDPS by aminobisphosphonates results in decreased levels of farnesyl pyrophosphate and geranylgeranyl pyrophosphate. Upon activation of T cells, farnesyl and geranylgeranyl moieties are transferred to the C termini of GTPases, allowing them to anchor in the inner leaflet of the plasma membrane and function in signal transduction. Prolonged exposure to aminobisphosphonates, therefore, would block signal transduction required for T cell proliferation and survival. Statin inhibition of HMGCR activity also works similarly (62). Besides blocking GTPases, statins reduce the association of Lck and linker of activation of T cells with membrane rafts in T cells (63). In our experiments, both aminobisphosphonates and statins blocked γδ and αβ T cell proliferation in response to a variety of different stimuli if sufficiently high doses were used. These results are consistent with reports of the broad immunologic effects of statin treatment in immune and autoimmune responses that do not involve γδ T cells (29–31, 64).

Ex vivo expansion of blood Vγ2Vδ2 T cells was also inhibited by continuous exposure to aminobisphosphonates. We observed highly variable levels of Vγ2Vδ2 T cell expansion (ranging from 17–33% of CD3 T cells; Fig. 2C) with narrow dose responses that were similar to the results of other studies (25–85% and 8–49%).
Aminobisphosphonate toxicity occurred with exposure periods as short as 6 h. However, pulsing aminobisphosphonates to limit T cell exposure resulted in uniform expansions of V\textsubscript{g}2V\textsubscript{d}2 T cells over a 10–30-fold dose range (Fig. 2D) rather than the 3–5-fold dose range commonly observed with continuous culture (66).

During the pulsing period, monocytes take up zoledronate through fluid phase endocytosis more efficiently than V\textsubscript{g}2V\textsubscript{d}2 T cells (67), thereby reducing T cell toxicity. Pulsing aminobisphosphonates replicates in vivo exposure because aminobisphosphonates are rapidly cleared through renal excretion (they are not metabolized) and by binding to bone such that they have a half-life of \(\sim 1–2\) h and less than 1% remain 24 h after infusion (68, 69). Aminobisphosphonates are being commonly used in clinical studies to expand V\textsubscript{g}2V\textsubscript{d}2 T cells ex vivo for adoptive transfer into cancer patients for immunotherapy (70–75). Our results suggest that pulsing of PBMCs for 4–6 h with higher aminobisphosphonate doses would give more consistent ex vivo expansions and potentially more vigorous V\textsubscript{g}2V\textsubscript{d}2 T cells for adoptive transfer.

**FIGURE 9.** siRNA downregulation of either FDPS mRNA or isopentenyl diphosphate isomerase mRNA in APCs results in indirect stimulation of V\textsubscript{g}2V\textsubscript{d}2 T cells with elevations in intracellular IPP levels in APCs. A, siRNA treatment greatly decreases mRNA levels of most enzymes in isoprenoid biosynthesis. mRNA levels of enzymes targeted by siRNA were measured in comparison with control siRNA using real-time PCR as detailed in the Materials and Methods. B, Downregulation of FDPS results in APCs that stimulate V\textsubscript{g}2V\textsubscript{d}2 T cells. HeLa cells were either untransfected or transfected with control siRNA or siRNA targeting mRNAs for enzymes required for the synthesis of isoprenoid compounds. After 72 and 96 h, transfected HeLa cells were mixed with HF.2 V\textsubscript{g}2V\textsubscript{d}2 T cells. Supernatants were harvested 16 h later, and the levels of IFN-\(\gamma\) (left panels) and TNF-\(\alpha\) (right panels) were determined by ELISA. For each enzyme, three siRNAs were tested with the best siRNA shown. Results are representative of three experiments. C, Increased intracellular IPP levels in HeLa cells after transfection with siRNA to FDPS. HeLa cells were transfected with either a control siRNA or an siRNA to FDPS. After 72 or 96 h, the cells were harvested and intracellular IPP level was measured. D, Stimulation by APCs treated with siRNA to FDPS is sensitive to statin inhibition. HeLa cells were transfected with siRNA to FDPS and after 72 h cultured with HF.2 V\textsubscript{g}2V\textsubscript{d}2 T cells in the presence of mevastatin. For comparison, untransfected HeLa cells were continuously cultured with 0.1 \(\mu\)M HMBPP or 1:4000 PHA, or they were pulsed with 1 mM risedronate with HF.2 T cells in the presence of mevastatin. Cultures were pulsed with 1 mCi of \([\text{3H}]\)-thymidine on day 1 and harvested 16–18 h later. E, Recognition of FDPS siRNA-treated APCs is mediated by the V\textsubscript{g}2V\textsubscript{d}2 TCR. The DBS43 V\textsubscript{g}2V\textsubscript{d}2 TCR transfectant or the parent mutant Jurkat cell line, J. RT3-T3.5, was cultured with HeLa cells treated with either a control siRNA or siRNA to FDPS and PMA or with anti-TCR\(\alpha\), ionomycin (1 \(\mu\)g/ml), or HMBPP (1 \(\mu\)M) in the presence of Va2 cells and PMA. The supernatants were harvested and IL-2 levels were assessed by proliferation of the IL-2-dependent HT-2 cell line. F, Downregulation of IDI renders APCs stimulatory for V\textsubscript{g}2V\textsubscript{d}2 T cells. Mitomycin C-treated HeLa cells were transfected with a control siRNA, three different siRNAs targeting IDI, or an siRNA targeting FDPS. HeLa cells were transfected with either a control siRNA or an siRNA to FDPS. After 96 h, transfected HeLa cells were mixed with HF.2 V\textsubscript{g}2V\textsubscript{d}2 T cells. Culture supernatants were harvested 16 h later, and IFN-\(\gamma\) (middle panels) and TNF-\(\alpha\) (right panels) were determined by ELISA. Proliferation was assessed on day 2 (left panels).
Besides pharmacologic inhibitors such as aminobisphosphonates, we found that downregulation of FDPS mRNA by siRNA makes tumor cells stimulatory for Vγ2Vδ2 T cells and that this stimulation is highly sensitive to statin inhibition. Our findings confirm a study reporting that short hairpin RNA for FDPS stably expressed by tumor cells makes the tumor cells stimulatory for Vγ2Vδ2 T cells (56). Moreover, we show that reductions in FDPS activity increase cellular IPP levels and that recognition of treated cells, like recognition of the Daudi and RPMI 8226 cell lines (47), is mediated by the Vγ2Vδ2 TCR.

Differences in the sensitivity to statin inhibition can help to distinguish between different pathways of stimulation of Vγ2Vδ2 T cells (26, 27). Indirect stimulation of Vγ2Vδ2 T cells by aminobisphosphonates, alkylamines, or siRNAs inhibiting FDPS, was more sensitive to statin inhibition than direct stimulation. However, the difference in statin sensitivity varied depending on the statin used (10–154-fold difference) and on the strength of stimulation. Statin inhibition of aminobisphosphonate responses was increasingly efficient when the Vγ2Vδ2 responses were less than 45% of the maximum response (Supplemental Fig. 4). In contrast, stimulation by prenyl pyrophosphates or the SEA superantigen was relatively resistant to statin inhibition over a broad response range, requiring concentrations similar to those required to inhibit γδ responses to IL-2 and PHA and αβ T cell responses to tetanus toxoid and IL-2. Therefore, because statins inhibit both indirect and direct Vγ2Vδ2 T cell responses, it is important to measure statin inhibition over a wide statin dose range in comparison with known Vγ2Vδ2 stimulators. When performed in this manner, sensitivity to statin inhibition distinguishes between indirect stimulation by FDPS inhibition and direct stimulation of Vγ2Vδ2 T cells.

Using statin inhibition, we studied alkyl-bisphosphonates, a new class of bisphosphonates that lack amino moieties. The amino moiety in aminobisphosphonates is critically important for FDPS inhibition (76) and for inhibiting bone resorption (77). However, we found that aminobisphosphonate analogs lacking this amino moiety stimulated Vγ2Vδ2 T cells, although requiring somewhat higher concentrations (EC50 of ~300–600 μM), Vγ2Vδ2 stimulation by an alkyl-bisphosphonate was highly resistant to statin inhibition with a dose response curve identical to the directly stimulating alkyl-pyrophosphate, n-propyl-pyrophosphate. In contrast, the similar aminobisphosphonate, pamidronate, was highly sensitive to statin inhibition (Fig. 8C). Given the differences in statin inhibition, we propose that the loss of the amino moiety switches aminobisphosphonates from indirectly stimulating through FDPS inhibition to directly stimulating Vγ2Vδ2 T cells (Fig. 10, top).

Like alkyl-bisphosphonates, HMB-CPCP is a phophonate compound that is an analog of HMBPP. Prenyl-pyrophosphonates (-CPOP), -methylene dihydropyrophosphonates (-OPCP), and -phosphor-ylmethylphosphonates (-CPCP) have identical carbon chains as natural prenyl pyrophosphates, but have phosphate linkages. The change in linkages affects their ability to stimulate Vγ2Vδ2 T cells. Changing both ester linkages in HMBPP to phosphate linkages (HMB-CPCP) reduces activity by 5.8 logs (681,000-fold). Much of this decrease can be attributed to the change of the pyrophosphate to a methylene dihydropyrophosphate, because (E)-1-hydroxy-2-methyl-pent-2-enyl pyrophosphate (HMB-COPP) is only 2.3-fold less active than HMB-OPCP (53), whereas HMB-OPCP is ~70,800-fold less active (34, 54). Despite the differences in activity, HMB-CPCP had similar low sensitivity to statin inhibition like HMBPP. Thus, phosphate analogs of prenyl pyrophosphates also appear to directly stimulate Vγ2Vδ2 T cells (Fig. 10, top).

HMB-OH is another analog of HMBPP that stimulates Vγ2Vδ2 T cells, although it totally lacks phosphate groups (34) that are generally required for stimulation (32). To determine its mechanism of stimulation, we first assessed HMB-OH responses for their sensitivity to statin inhibition. Like HMBPP, HMB-OH was relatively resistant to inhibition, suggesting that HMB-OH does not inhibit FDPS to stimulate Vγ2Vδ2 T cells. Further confirming this hypothesis, there were no increases in cellular IPP after treatment with HMB-OH. Another possibility is that HMB-OH enters cells, becomes phosphorylated to HMBPP, and is secreted for stimulation. Some isoprenoid alcohols likely rescue aminobisphosphonate-blocked cells in this way, presumably because of a two-step salvage pathway (78–82). However, there was no evidence of extracellular HMBPP during HMB-OH stimulation given that the addition of alkaline phosphatase had no effect (Fig. 6C) but totally abrogated stimulation by HMBPP. Phosphorylation of HMB-OH might also be expected to be at least partially dependent on APCs. However, HMB-OH stimulated Vγ2Vδ2 T cells with kinetics identical to HMBPP and IPP, unlike ApppI that was partially dependent on APCs as reported earlier (51). Moreover, HMB-OH stimulates Vγ2Vδ2 T cells at concentrations similar to those required by HMB-CPCP and HMB-OPCP that are directly presented. Therefore, we propose that HMB-OH is directly presented (Fig. 10, bottom) and that phosphate groups are not absolutely required for stimulation of Vγ2Vδ2 T cells.
In conclusion, stimulation of VγVδ2 T cells can be classified as either direct or indirect. For direct stimulation, compounds such as prenyl pyrophosphates, prenyl pyrophosphonates, and alkyl-bisphosphonates associate with an unidentified protein at the cell surface for direct presentation to the VγVδ2 TCR (Fig. 10, top). In contrast, aminobisphosphonates and alkylamides use an indirect pathway to stimulate VγVδ2 T cells (Fig. 10, middle). These compounds enter APCs and block the FDPs enzyme, leading to the accumulation of IPP that is then transported through an unknown process to the cell surface, where it stimulates VγVδ2 T cells. siRNAs for FDPs and IDI decrease enzyme levels thus diminishing their action, resulting in IPP accumulation that directly stimulates VγVδ2 T cells. Indirect stimulation due to blocking FDPs (and likely IDI) function is highly sensitive to statin inhibition of the upstream HMGCR enzyme, because the accumulation of IPP is dependent on metabolite flow down the pathway. Exogenous mevalonate, the rate-limiting metabolite, will increase intracellular IPP levels if present at a high concentration (Fig. 10, bottom); however, in this situation, statins will not easily block this indirect stimulation. Finally, HMB-OH is likely directly presented to the VγVδ2 T cells because its stimulation is statin and alkaline phosphatase resistant, does not increase IPP levels, is active at similar concentrations as HMB-CPPC, and is independent of APCs, like HMBPP (Fig. 10, bottom). Our results demonstrate that there are multiple ways to stimulate VγVδ2 T cells. Further characterization of these indirect and direct pathways will deepen our understanding of the roles of γδ T cells in human immunity and may improve current approaches to cancer immunotherapy using VγVδ2 T cells.
