Increased T Cell Proliferative Responses to Islet Antigens Identify Clinical Responders to Anti-CD20 Monoclonal Antibody (Rituximab) Therapy in Type 1 Diabetes

Kevan C. Herold,§ Mark D. Pescovitz,† Paula McGee,‡ Heidi Krause-Steinrauf,‡ Lisa M. Spain,§ Kasia Bourcier,§ Adam Asare,§ Zhugong Liu,§ John M. Lachin,§ H. Michael Dosch,‖ and the Type 1 Diabetes TrialNet Anti-CD20 Study Group¹

Type 1 diabetes mellitus (T1DM) reflects the progressive, T cell-mediated destruction of insulin-producing β-cells in the pancreatic islets of Langerhans (1, 2). The current model of pathogenesis has deep roots in studies of the spontaneously diabetic NOD mouse in which T cells, reactive to islet and neuronal Ags, can adoptively transfer disease in the absence of other accessory cells (3, 4). Similar T cell autoreactivities can be identified in NOD mice and in patients with T1DM (5, 6). Although nearly always measured in the peripheral blood of patients (i.e., the systemically recirculating immune compartment), these T cells likely reflect the diabetic pancreas immune attack, as their specificities are similar in NOD mice in which pathogenicity can be confirmed by adoptive disease transfer. Direct demonstration of pathogenicity has been impossible in humans, but in mouse models, β-cell killing by T cells has been shown (7).

We previously validated the ability of cellular assays to measure T cell proliferative responses to diabetes-associated Ags in the T1DM and the relationship of such T cell pools to disease progression are still under study.

Although much attention has been devoted to diabetes-associated (but not tissue-toxic) autoantibodies, a pathogenic role for B lymphocytes emerged from the disease protection observed in B cell-deficient NOD congenics (11–13), later linked to unique B lymphocyte-mediated Ag presentation to T cells (14, 15). Recent interest focused on the role of B cells late in prediabetes, in which B cell depletion with anti-CD20 mAb reversed new-onset type 1 diabetes in a subset of treated NOD mice (16). This observation was translated to patients in the randomized, placebo-controlled TrialNet Rituximab (anti-CD20) trial (17). This trial compared the effects of four weekly rituximab or placebo injections, in new-onset patients, on C-peptide preservation and metabolic measures, including hemoglobin A1c levels and insulin usage. All parameters were improved by rituximab treatment for as long as 1 y after study entry. The lowest B lymphocyte counts were measured at the earliest time point, 5 wk after initiation of
therapy, and by 12 mo, the circulating B lymphocytes had recovered to 69% of the baseline levels. Serum levels of IgG were not significantly different in the control and drug-treated subjects at that time, but the levels of serum IgM were still reduced 1 y after rituximab therapy.

The mechanisms of anti-CD20 effects are not clear because ultimately disease and disease progression are T cell dependent (17). To determine how B cell depletion with anti-CD20 mAb impacted disease-associated cellular immune responses, we compared T cell subset distributions and autoreactivity profiles in rituximab recipients who had positive C-peptide responses with those unresponsive to treatment.

Materials and Methods

Subjects and clinical samples

A detailed description of the TrialNet Rituximab trial (NCT00279305) and the baseline characteristics of the study subjects have been published (17). Briefly, 87 subjects were randomized in a 2:1 ratio to rituximab or placebo treatment, of which 81 formed the intention-to-treat (ITT) population, and 78 of whom completed the 1-y mixed-meal tolerance test (MMTT; the basis for the primary outcome, the area under the curve [AUC]). Based on the change in the AUC of the C-peptide response from baseline to 6 mo, each participant was designated as a C-peptide responder or nonresponder.

Of the ITT cohort, 75 (93%) were included in the flow analysis and 80 (99%) in the T cell proliferation (TCP) studies described in this article. Samples were collected for flow cytometry at baseline (prior to study drug dosing), 5 wk, and 3, 6, and 12 mo after the first dose of study drug. T cell assays were performed at baseline and 6 and 12 mo after the first dose of study drug. Institutional Review Board approval was obtained for these measurements as part of trial participation.

Flow cytometric analysis

Whole blood was shipped overnight at ambient temperature to the Immune Tolerance Network Flow Cytometry Core (Roswell Park Cancer Institute, Buffalo, NY). Abs used in this study were purchased from BD Biosciences (San Jose, CA). Standard methods were used for staining of cells including blocking Fc receptors with mouse IgG. Cocktails of fluorochrome-labeled mAbs to CD3, CD4, CD8, CD62L, and CD25 were used, and the flow cytometric analysis was performed using an FACScanto (BD Biosciences) flow cytometer. The flow cytometry data were analyzed using WinList software.

TCP assay

PBMCs were isolated by Ficoll-Hypaque gradient centrifugation from fresh blood samples shipped to the T Cell Core Laboratory at the Hospital For Sick Children (Toronto, ON, Canada). The washed cells were seeded (1 \times 10^5 cells/mL) into flat-bottom microplates containing test or control Ags in 200 μL in serum- and protein-free Ex-Cell Hybri-Max medium (Sigma-Aldrich, St. Louis, MO). Test Ags were used at 1–4 concentrations (0.1–10 μg/mL), depending on cell yields. Ten units recombinant human IL-2 were added to all test wells (8, 9, 18). Depending on the blood volume sent and viable cell numbers, not all Ags could be used in all tests. Cultures were incubated (37°C, 5% CO2) for 5 d, receiving a [3H]thymidine pulse (1 μCi/mL) at 4 d, followed by a wash to remove any unincorporated thymidine. The cultures were harvested (8, 9, 18). In most cases, the cultures were counted in a [3H]thymidine counter. To compare the number of lymphocytes in each group, the number of CD3+,CD4+,CD8+, activated CD4+CD25+ T cells, or regulatory T cells (Tregs) were not significantly different in the placebo-treated subjects showed a decline of C-peptide responses (p = 0.038). After 6 mo, there was a parallel decline in both study groups, but a significant difference remained between the groups in average responses over 12 mo (p = 0.0013).

Based on the observed change in C-peptide responses relative to the coefficient of variation (CV) of repeated measurements, 58% of the subjects in the rituximab-treated group were responders. The age and sex distribution, prevalence of autoantibodies at baseline, HLA genotypes, and baseline MMTT C-peptide responses were similar between responders and nonresponder groups (Table I).

Analysis of lymphocyte subsets by flow cytometry

In rituximab recipients, the total lymphocyte counts had fallen to 87.6% of baseline by 3 mo (Fig. 1A, p < 0.001), but recovered later as measured at 6 and 12 mo. The decline was accounted for by depletion of CD19+ B cells. With some fluctuation, the placebo group remained at an average of 107.7% of the baseline lymphocyte count over the first year. Using ANCOVA to compare treatment groups, the number of CD3+, CD4+, CD8+, activated CD4+CD25+ cells, or regulatory T cells (Tregs) were not significantly different in the rituximab and placebo groups over the 1-y study period (Fig. 1B–F; p values >0.05).

T cell studies

We compared ex vivo T cell proliferative responses to an array of test and control Ags as described (8, 9, 21) in responders and nonresponders to rituximab treatment as well as placebo recipients. The baseline responses to disease-associated test Ags were of ≥4 was considered evidence for the presence of autoimmunity in a given sample.
similar in the two treatment groups and in the drug responders and nonresponders (Table II). Using the definition of a positive response in the assay overall as an SI of $1.5$ to at least four Ags, $75\%$ of the rituximab- and $82\%$ of the placebo-treated subjects showed positive T cell autoreactivity at baseline ($p = \text{NS}$), with similar incidence and response amplitudes of positive responses to each of the 12 individual disease-associated Ags (mean SI was $2.02 \pm 0.66$ in the rituximab-treated and $2.28 \pm 0.72$ in the placebo-treated group; $p = \text{NS}$). There were also no differences when test Ags were thematically clustered (Fig. 2, Table II).

At months 6 and 12, T cell autoreactivities in the two treatment groups were also similar (Fig. 3, Table II). Although the differences in the percentage of positive responses were not statistically significant between groups for any specific Ags or overall at either 6 or 12 mo, for all 12 Ags, the proportion positive was higher in the rituximab- versus placebo-treated subjects at 6 mo, but not at 12 mo ($p = \text{NS}$).

Fisher’s exact test and Wilcoxon rank sum test were used for treatment and responder comparisons. Means and SDs are reported for continuous variables. For categorical variables, the number and percent are reported. AUC mean denotes the corresponding mean in pmol/ml computed as AUC/120 min.

*One rituximab subject was not evaluated at 6 mo and could not be classified as a responder or nonresponder.

![FIGURE 1. Analysis of lymphocyte subsets in patients treated with rituximab or placebo. The number of total lymphocytes, CD3+, CD8+, CD4+, activated CD4+ (CD4*CD25*), and Tregs (CD4*CD25*CD62Li) cells and 95% CI for the mean are shown for both treatment arms at the indicated time points (•, rituximab; □, placebo). The number of lymphocytes was significantly reduced at 5 and 12 wk in the rituximab-treated compared with the placebo-treated group ($p < 0.01$). The number of circulating CD3+CD4+ T cells was higher and lower in the rituximab-treated group at 5 ($p < 0.03$) and 12 ($p < 0.02$) wk, respectively, but overall, the differences in the total CD3+ T cell counts in the two treatment arms were not statistically significant ($p = 0.89$). The number of circulating CD4+ T cells was significantly increased in the rituximab-treated group at 5 and 12 wk ($p < 0.05$), but was overall not different between the treatment arms ($p = 0.65$). The number of circulating CD8+ T cells was significantly lower in the rituximab-treated group at 12 wk ($p < 0.02$) but not statistically different over the 12 mo ($p = 0.68$). The numbers of subjects per group at each time point were the following (rituximab, control): baseline (52, 29), week 5 (47, 22), week 12 (47, 27), week 26 (48, 26), and week 52 (44, 26).
Similarly, the SIs were not significantly different for any of the Ag groups or any of the individual Ags. However, sizable differences emerged when grouping rituximab recipients into C-peptide responders versus nonresponders (Fig. 3, Table III). In the rituximab group at 6 mo, 86.7% of subjects had a positive response overall, whereas 96.5% of responders versus 75.2% of nonresponders were positive \((p = 0.028)\). There was a significant increase in the responses to 9 of the 12 Ags tested in the responders compared with the nonresponders. At month 12, these differences were reduced; only the proportion of responses to EX2 and MBP were significantly greater in C-peptide responders \((p = 0.037)\) and neuronal \((0.043)\) Ag groupings (Table III). Over 6 and 12 mo combined, the association was statistically significant for 8 out of the 12 test Ags (S-100, GAD, GAD555, PI, ABBOS, BLG, BSA, and casein), for each grouping (islet: \(p = 0.01\); neuronal: \(p = 0.048\); milk: \(p = 0.006\)), and overall \((p = 0.009)\). These differences were the result of treatment with rituximab because we did not detect any significant differences in responders and nonresponders at baseline (Supplemental Table II).

Importantly, the positive and negative proliferative control responses were similar in C-peptide responders and nonresponders \((p = 0.519 \text{ and } 0.425, \text{ respectively})\). The responses to tetanus toxoid were 12.95 (confidence interval [CI] 11.24–14.65) in the responders and 12.04 (CI 9.9–14.19) in the nonresponders. The extent of in vivo B cell depletion by rituximab, which was not significantly different in responders and nonresponders, did not appear to account for the differences in the T cell responses. When corrected for the number of CD19 cells or the same B cell subsets, there was minimal effect on the \(p\) values that describe the differences in the frequency of responses at 6 mo (data not shown).

![Figure 2](http://www.jimmunol.org/)

**FIGURE 2.** Average SIs in the TCP assay for each Ag group using cells from rituximab- or placebo-treated patients. The average SI (sum of [cpm for each analyte/cpm for media alone]/number of analytes) and 95% CIs for the mean for the positive control analytes, negative control analytes, total diabetes Ags, and thematically grouped Ags: islet, neuronal, and milk are shown for the rituximab-treated (●) and placebo (●) groups at the three study time points. None of the differences between the two groups are of statistical significance. The numbers of subjects per group at each time point were the following (rituximab, control): baseline (49, 29), month 6 (49, 27), and month 12 (46, 28).

Estimates of percent positive as a function of treatment group for each Ag, and overall, from a separate logistic model at 6 or 12 mo adjusted for baseline positivity comparing treatment group. None of the differences between the rituximab and control groups are nominally statistically significant at \(p \leq 0.05\).
Relationship of cellular and metabolic responses

We regressed the log (C-peptide + 1) values on the T cell proliferative responses (SI) at 6 and 12 mo, separately and jointly, adjusting for age, sex, and the SI and C-peptide responses at baseline. Within the rituximab group, Fig. 4 shows that the C-peptide increased as the SI increased (a positive relationship) at 6 mo for all of the Ags and groups of Ags, six of which were statistically significant: S-100 ($p = 0.022$) and PI ($p = 0.033$), as well as milk Ags overall ($p = 0.021$), ABBOS ($p = 0.029$), BLG ($p = 0.017$), and BSA ($p = 0.029$). Conversely, within the placebo group, there was in inverse association (C-peptide decreased as the SI increased) for all Ags and Ag groupings, though not significantly so for any one in particular. Neither the negative nor positive controls were associated with C-peptide responses.

In like analyses within the placebo group, there was no significant relationship between 6 and 12 mo C-peptide levels and any Ag responses (Fig. 4 and data not shown). Further analyses of the two groups combined showed that the relationship between the change in C-peptide/change in SI was significantly different between the rituximab versus placebo groups (i.e., the test of the group*SI interaction) for all 16 of the Ags and Ag groupings. In a similar comparison between responders and nonresponders to rituximab, we found a significant difference between responders and nonresponders for each analyte for the slope of percent change in C-peptide/unit change in SI (Fig. 4B). However, within the nonresponders, none of these slopes were significantly different from zero. Within the responders, there were three analytes with a slope significantly different from zero: PI, ABBOS, and BLG ($p < 0.05$).

Lymphocyte subsets in subgroups of rituximab recipients

We compared the relative and absolute number of T cell subsets in C-peptide responders and nonresponders within the rituximab-treated group (Fig. 5). By an ANOVA for repeated measures,
The absolute number of CD19⁺ cells over 12 mo was not significantly different in C-peptide responders and nonresponders ($p = 0.41$), but the number of CD3⁺ cells was higher in the responders (1512, CI: 1422, 1608 versus 1346, CI: 1255, 1444; $p = 0.016$). The most significant differences between the groups were accounted for by an increase in the number of CD4⁺ cells (937, CI: 878, 999 versus 822, CI: 764, 884; $p = 0.01$) because the number of CD8⁺ cells was only slightly different (423, CI: 393, 454 versus 383, CI: 353, 417; $p = 0.08$). However, to assess this hypothesized effect of CD4 cells among responders and nonresponders, we conducted additional analyses adjusting for the CD4 values at baseline, week 5, month 3, and month 6 of the positivity/negativity of each analyte. There was very little change in the $p$ values, and 9 out of the 13 (versus 10 out of 13 without adjustment) were still significant at the 0.05 level. The number of activated, CD4⁺CD25⁺ cells was not significantly different in responders and nonresponders. The number of Tregs (CD4⁺CD25⁺CD62L⁺) was higher at week 12 (48, CI: 41, 57 versus 34, CI: 28, 41; $p = 0.005$) in responders, but over the 12-mo period with four separate measurements, the differences were not statistically significant ($p = 0.17$).

Discussion

This trial discovered that enhanced, T cell proliferative responses to diabetes-associated target Ags are predictive of a positive C-peptide response to rituximab in newly diagnosed patients with T1D. Enhanced T cell reactivity in C-peptide responders was not explained by overall elevated T cell reactivity, because neither positive nor negative control responses were changed by therapy, nor could any control responses be associated with stimulated C-peptide levels. The enhanced T cell reactivity cannot be explained by an artifact or assay drift. Background counts were not significantly different between C-peptide responders and nonresponders at 6 mo ($p = 0.632$), and positive ($p = 0.519$) and negative ($p = 0.425$) controls were unchanged in the same assays. There was also no change in T cell reactivity of placebo recipients. We conclude that the observed elevation of Ag-specific responses to diabetes-associated environmental, islet, and neuronal Ags was caused by rituximab-driven attenuation of postonset β-cell loss over the first year posttherapy. These strictly blinded assays, conducted over a 27-mo period, delineated an almost absolute (95.6%) linkage between enhanced T cell reactivity and the presence of definitive signs of β-cell preservation. It was conceivable that increased proliferative responses were a function of being a clinical responder per se and not due to the effects of the rituximab treatment. Comparing the change in SIs with C-peptide AUC in both study arms, we found that the positive association between changes in C-peptide responses only occurred in rituximab recipients. In the placebo group, this relationship was more often negative. Thus, the observed changes in T cell responses were a function of the rituximab therapy received rather than sequelae of the improved metabolic response.

In addition, our findings cannot be explained by differences in the extent of B cell depletion. The number of circulating T cells overall were not significantly different in the rituximab- and placebo-treated groups. We found modest but statistically significant changes in CD3⁺ and CD4⁺ T cells, but the mechanistic relevance of these minimal changes in polyclonal populations to the Ag-specific responses is not clear. Even if subtle, a numeric expansion of the T cell compartment might reflect brief homeostatic proliferation into hemopoietic space, vacated by rituximab. The observation that this space was only 69% refilled by B lineage cells 1 y after the single treatment course as well as the growth of the T cell compartment both support the homeostatic expansion scenario. This expansion might include the Ag-specific T cell pools we measured ex vivo. There is precedence for this with rapid diabetes development in lymphocyte-free NOD.scid mice following transfer of small numbers of diabetogenic wild-type NOD lymphocytes or following lymphotoxic therapy of wild-type NOD mice with cyclophosphamide (22, 23). However, homeostatic expansion alone does not appear to explain the differences in the TCP assay in responders and nonresponders because the responses to control Ags were not different between these two groups, yet the responses to the diabetes-related Ags were different. This suggests that there has been expansion of disease Ag-specific T cells and/or function.

However, in the present trial, loss of β-cells/insulin secretory reserve was not accelerated but significantly slowed. Thus, therapeutic B cell depletion relieved a somewhat counterintuitive, disease progression-associated restraint of T cell expansion. These data demonstrate, for the first time in human T1D to our knowledge, a progression-promoting role of B lineage cells at diabetes onset. This B cell role is amenable to therapeutic intervention and adds a fundamental similarity to T1D pathogenesis in NOD mice and in humans. We conclude, therefore, that the statistically significantly different relationships between C-peptide and T cell

![FIGURE 4. Association of the change in TCP SI with the change in C-peptide AUC at month 6 in the rituximab- and placebo-treated groups. A. The percent change in SI/percent change in log (C-peptide AUC) + 1 is shown for rituximab (squares) and placebo-treated (triangles) subjects. In subjects treated with rituximab, the open squares designate changes that are significantly associated. The changes in the placebo group are all negatively associated with the changes in C-peptide, but none are of statistical significance, whereas the relationship is positive in the rituximab-treated group, and the responses to S-100, PI, Abbos, BLG, and BSA are significantly associated ($p < 0.05$). B. A similar analysis is shown for responders (circles) and nonresponders (inverted triangles) in the rituximab group. There is a significant difference between responders and nonresponders for each analyte ($p < 0.0001$). However, within the nonresponders, none of the slopes are significantly from zero. The slopes for three of the Ags (PI, Abbos, and BLG) are significantly increased from zero in the responder group (open symbols, $p < 0.05$).]
responses between the rituximab and placebo groups show that the T cell responses between responders and nonresponders suggest a biological effect of rituximab treatment and not a general response regardless of the treatment received.

Our findings cannot be explained by chance alone, but it is important to note that the statistical relationship that we identified with the T cell assay has an unclear biologic foundation. We do not have a confirmatory assay in which the number of Ag-specific cells or the magnitude of their responses to Ags can be confirmed, and the mechanism that accounts for the increase in the proliferative responsiveness to disease-associated Ag-specific T cells is not clear.

The TCP assay is performed in the presence of IL-2, and therefore, it is also possible that the increased proliferative response that we found was due to an increased proportion of activated or anergic CD4+ or CD8+ T cells (21). Indeed, our flow cytometric analysis of peripheral blood cells did show a modest increase in the proportion of CD4+ and CD8+ T cells that expressed CD25 but the frequency of CD4+ or CD8+ T cells (21). It is also possible that B cell depletion altered T cell trafficking rather than purely numeric change in the Ag-specific T cells. For example, Piccio et al. (24) recently reported that there was a decrease in the number of T cells in the CSF after rituximab treatment of patients with relapsing/remitting multiple sclerosis. They suggested that B cells may be critical for T cell trafficking into the CNS inflammatory lesions. An analogous reduction in T cell trafficking into the islet following B cell depletion with the mAb might account for an increase in the number of Ag-specific cells in the periphery. A similar mechanism might be operative to explain the increase in the number of Ag-specific cells in the patients, have regulatory function by virtue of production of cytokines such as IL-10 or TGF-β or through other mechanisms (25, 26). Further studies of the cytokines that are made by the T cells in response to Ag might be helpful in addressing this question. The mechanism that would lead to induction of T cells with this phenotype has not been identified, but it is of note that IL-10-secreting B lymphocytes have been identified, and the secretion of this cytokine might create an environment that induces differentiation of T cells that produce regulatory cytokines. Induction of Tregs might be postulated to occur through a bystander mechanism in the presence of IL-10 production by B cells that repopulate after CD20 depletion (i.e., regulatory B cells) (26, 27).

Collectively, we have found that proliferative responses to diabetes-associated target Ags are similar in patients who receive antirituximab compared with placebo. However, among those treated with rituximab, individuals who are clinical C-peptide responders show an increased proliferative response to islet, neuronal, and disease-relevant environmental Ags, and the changes in proliferative responses to islet Ags are associated with an increase in insulin secretory function. The perhaps simplest explanation of our data would be that rituximab allowed recovery and/or regeneration of β cells through transient interruption of pathogenic T cell recruitment via surface Ig-captured autoantigen but
providing new β-cell targets during recovery of the CD19+ B cell compartment posttreatment (28).

Disclosures
M.D.P. has been a speaker and consultant to Roche/Genentech and has received research support for a clinical trial from Genentech. The other authors have no financial conflicts of interest.
