Vitamin D Inhibits Monocyte/Macrophage Proinflammatory Cytokine Production by Targeting MAPK Phosphatase-1

Yong Zhang,* Donald Y. M. Leung,*† Brittany N. Richers,* Yusen Liu,‡§ Linda K. Remigio,* David W. Riches,* and Elena Goleva*

It is estimated that 1 billion people around the world are vitamin D deficient. Vitamin D deficiency has been linked to various inflammatory diseases. However, the mechanism by which vitamin D reduces inflammation remains poorly understood. In this study, we investigated the inhibitory effects of physiologic levels of vitamin D on LPS-stimulated inflammatory response in human blood monocytes and explored potential mechanisms of vitamin D action. We observed that two forms of the vitamin D, 1,25(OH)2D3 and 25(OH)D3, dose dependently inhibited LPS-induced p38 phosphorylation at physiologic concentrations, IL-6 and TNF-α production by human monocytes. Upon vitamin D treatment, the expression of MAPK phosphatase-1 (MKP-1) was significantly upregulated in human monocytes and murine bone marrow-derived macrophages (BMM). Increased binding of the vitamin D receptor and increased histone H4 acetylation at the identified vitamin D response element of the murine and human MKP-1 promoters were demonstrated. Moreover, in BMM from MKP1−/− mice, the inhibition of LPS-induced p38 phosphorylation by vitamin D was completely abolished. Vitamin D inhibition of LPS-induced IL-6 and TNF-α production by BMM from MKP-1−/− mice was significantly reduced as compared with wild-type mice. In conclusion, this study identified the upregulation of MKP-1 by vitamin D as a novel pathway by which vitamin D inhibits LPS-induced p38 activation and cytokine production in monocytes/macrophages. The Journal of Immunology, 2012, 188: 2127–2135.

Vitamin D is well known for its role in calcium homeostasis and maintenance of bone metabolism (1). However, recent evidence suggests that vitamin D plays important roles in both innate and adaptive immunity (2). Vitamin D levels are routinely tested by assessing the concentration of the major circulating form of the vitamin D, 25(OH)D3, in serum; this form of vitamin D has a half life of 15 d, whereas the active form of vitamin D, 1,25(OH)2D3, has a short half life of ~15 h (3–5).

1,25(OH)2D3 acts as a ligand for the vitamin D receptor (VDR), a member of the nuclear receptors superfamily (6). VDR forms a heterodimer with a retinoid X receptor and regulates gene expression by binding to the vitamin D response element (VDRE). VDRE had been shown to be predominantly located in introns and intergenic intervals (7). VDRE is characterized by direct repeats of two hexameric core-binding motifs (preferentially being AGTTCA) spaced by three nucleotides (8, 9). The binding of VDR to VDRE recruits coactivators and enzymes with histone acetylation activity, causing the structural changes in chromatin, therefore, facilitating gene transcription (10).

LPS, a component of the Gram-negative bacterial cell wall, induces cytokine production by monocytes/macrophages. LPS has been implicated in sepsis caused by Gram-negative bacteria and induces intense inflammatory and procoagulant responses, which can be lethal (11). LPS is recognized by cell surface TLR4, which initiates intracellular signal transduction cascades (12). The MAPKs activated by LPS [ERK, JNK, and p38 (12)] are critical regulators of proinflammatory cytokine production, including TNF-α and IL-6 (13, 14). Although these proinflammatory cytokines enhance host defense, excessive production leads to unresolved inflammation (15). Therefore, feedback control of MAPK activation is necessary. MAPK phosphatases (MKP) inactivate MAPKs by dephosphorylating conserved threonine and tyrosine residues of the activated MAPK (16). MKP-1 is known to preferentially inactivate p38 and JNK, leading to subsequent inhibition of proinflammatory cytokines production (17, 18). In the current study, we examined mechanisms of the vitamin D-mediated suppression of LPS-activated monocytes/macrophages. We found that vitamin D inhibits LPS-induced cytokine production by upregulating MKP-1, thereby attenuating p38 activation.

Materials and Methods

Materials

1,25(OH)2D3, 25(OH)D3, and monoclonal anti–β-actin Ab were purchased from Sigma-Aldrich (St. Louis, MO). HyQTagase was purchased from HyClone Laboratories (Logan, UT). TrypLE Express was purchased from Invitrogen (Carlsbad, CA). Phosphorylated (p)-p38 and p38 Abs were purchased from Cell Signaling Technology (Danvers, MA). Anti-mouse and anti-rabbit HRP-labeled IgG were purchased from Amersham Biosciences (Piscataway, NJ). Rabbit polyclonal Ab to VDR, rabbit polyclonal Ab to MKP-1, Radioimmunoprecipitation Assay Lysis Buffer, and protein A/G PLUS-agarose beads were purchased from Santa Cruz Biotechnology (Santa Cruz, CA). Rabbit polyclonal Ab to histone H4 and acetylated histone H4 as well as the Magna Chromatin Immunoprecipitation (ChIP) A/G ChIP Kit were purchased from Millipore (Temecula, CA). Chemilu-
miniscence reagents were purchased from Perkin-Elmer Life Sciences (Waltham, MA). All the reagents and conjugated Abs against p-p38, p-ERK1/2, p-JNK, and IL-6 in flow cytometry analysis were purchased from BD Biosciences (San Diego, CA), whereas the TLR4 Ab was purchased from ebioscience (San Diego, CA).

**Study subjects**

Blood samples were collected from normal healthy adults. Approval was received from the National Jewish Health Institutional Review Board (Denver, CO) for the study.

**Mice**

C57BL/6 × 129 mice were purchased from The Jackson Laboratory (Bar Harbor, ME). MKP-1−/− mice were provided by Bristol–Myers Squibb (19). Six- to 8-wk-old males were used in the experiments. All experiments using these animals were approved by the Institutional Animal Care and Use Committee at National Jewish Health. This institution has an animal welfare assurance number (A3026-1) on file with the Office of Protection and Research Risks.

**Cell culture and treatment**

PBMC were isolated from heparinized, venous blood of healthy donors by Ficoll–Hypaque density gradient centrifugation as described elsewhere. PBMC were cultured in hormone-free medium (phenol-red free RPMI 1640 medium containing 5% charcoal-stripped FCS, 50 μg/ml streptomycin, and 50 U/ml penicillin) with a range of doses of 1.25(OH)2D3 or 25(OH)D3 for 24 h at 37°C with 5% CO2. Equal volume of ethanol was used as vehicle control. Following pretreatment with vitamin D, the cells were stimulated with 10 ng/ml LPS, and the effects of vitamin D on LPS responses in CD14+ monocytes were examined.

Bone marrow cells from wild-type (C57Bl/6 × 129) and MKP−/− mice were isolated as previously described (20, 21) and cultured in DMEM containing 10% FBS, 10% L929 cell-conditioned medium (as a source of CSF-1), 50 μg/ml streptomycin, and 50 U/ml penicillin at 37°C with 5% CO2 for 5 d to produce bone marrow-derived macrophages (BMM).

**Flow cytometry analysis**

To analyze the effects of vitamin D on p38 activation by LPS, PBMC were preincubated in hormone-free medium containing 1.25(OH)2D3 or 25(OH)D3 for 24 h, followed by stimulation with 10 ng/ml LPS for 10 min. Cells were then fixed with 2% formaldehyde at 37°C for 10 min. Adherent cells were collected by using HyQTase and Tryple Consecutively and combined with suspended cells. Cells were permeabilized in 500 μl 1× perm/wash buffer I (BD Pharmingen) at 4°C for 30 min, incubated in 100 μl 1× perm/wash buffer I containing FITC-conjugated anti-CD14 and allophycocyanin-conjugated anti–p-p38 Abs at 4°C for 1 h, and washed with 1× perm/wash buffer I. The samples were then analyzed by flow cytometry (BD FACSCalibur Flow Cytometer; BD Biosciences, Franklin Lakes, NJ) and CellQuest Pro software. The flow data were displayed as a percentage of CD14+ cells that express p-p38 (the gate for p-p38+ cells was set on the basis of isotype control binding).

To examine the effects of vitamin D on IL-6 production by LPS-activated monocytes, PBMC were cultured in hormone-free medium containing 1.25(OH)2D3 or 25(OH)D3 for 24 h, followed by 10 ng/ml LPS stimulation for 6 h with GolgiPlug added for the last 4 h of the incubation. Cells were collected as above and stained with allophycocyanin-conjugated anti-CD14 Ab in staining buffer at 4°C for 30 min. The cells were permeabilized in 500 μl 1× perm/wash buffer at 4°C for 30 min, incubated in 100 μl 1× perm/wash buffer containing FITC-conjugated anti–IL-6 Ab at 4°C for 30 min, and washed with 1× perm/wash buffer before testing on FACSCalibur as above.

**Real-time PCR**

Total RNA from human PBMC and murine BMM at the specified time point was prepared using the RNeasy Mini kit (Qiagen, Valencia, CA). After reverse transcription, 500 ng cDNA from each sample was analyzed by real-time PCR using the dual-labeled fluorogenic probe method on an ABI Prism 7300 real-time PCR system (Applied Biosystems). The expression of human and murine β-actin, TNF-α, IL-6, and human MKP-5 mRNA was determined. All primers were purchased from Applied Biosystems (Foster City, CA).

**Western blot analysis**

Whole-cell extracts were prepared by incubating cells with radioimmunoprecipitation assay lysis buffer with protease inhibitors on ice for 30 min, followed by centrifugation at 4°C for 10 min and collection of supernatants. Protein samples from vitamin D/LPS-treated PBMC and murine bone marrow cultures were resolved on Invitrogen 4–12% Bis-tris gel and transferred to polyvinylidene difluoride membranes. The membranes were incubated in PBS containing specific Abs, 5% dry milk, and 0.1% Tween 20 at 4°C overnight. Subsequently, membranes were washed in PBS/0.1% Tween 20, incubated for 1 h at room temperature with HRPlabeled secondary Abs, washed, incubated with chemiluminescent reagent, and processed for immunodetection. Densitometry was used to evaluate the intensity of the bands.

**ELISA analysis**

PBMC and murine BMM were treated with 1,25(OH)2D3 or 24 h, followed by 10 ng/ml LPS stimulation for 24 h. Supernatants were collected, human IL-6 levels from PBMC were tested using the Human IL-6 ELISA ready-set-go! Kit, and murine IL-6 and TNF-α levels from BMM were tested using the Mouse IL-6 ELISA ready-set-go! Kit and the Mouse TNF-α ELISA ready-set-go! Kit, respectively. All the ELISA kits were purchased from ebioscience (San Diego, CA).

**ChIP assay**

VDR binding to VDRE and histone H4 acetylation at the murine MKP-1 promoter were assessed using the Magna ChIP A/G ChIP Kit following the manufacturer’s instructions. VDR binding to VDRE and histone H4 acetylation at the murine MKP-1 promoter were assessed by ChIP assay as previously described (22) with modifications. Briefly, 2 × 10⁶ cells were used in each precipitation. After sonication, chromatin solution was pre-cleared with 30 μl protein A/G PLUS-agarose beads and 10 μg herring DNA at 4°C for 2 h and incubated with specific Ab or isotype control at 4°C overnight, followed by precipitation with 50 μl protein A/G PLUS-agarose beads at room temperature for 2 h. Precipitated chromatin complexes were removed from the beads through incubation at 65°C for 30 min with elution buffer (50 nM Tris [pH 8], 1 mM EDTA, and 1% SDS). A total of 200 μl eluate was mixed with 10 μl 5 M NaCl and 0.5 μl RNase A (DNase-free; 10 mg/ml) and incubated at 65°C overnight. Precipitated DNA was quantified by real-time PCR using SYBR green (Applied Biosystems). Primers used to detect the potential VDRE in the murine MKP-1 promoter were as follows: 5′-ACCTGTTGATCTCTGAGCAGT-3′ (E4.7 forward) and 5′-CTTGGAGATGGATTCCTCTCTA-3′ (E4.7 reverse). Primers used to detect the potential VDRE in the murine MKP-1 promoter were as follows: 5′-ACCCCTTGTCCCTCCCAAGGTCT-3′ (E33 forward), 5′-AGAGTTAACACCAACGACCACAAAT-3′ (E33 reverse), 5′-ACGAGGCGAGATGCTTATTAATTCTC-3′ (E09.9 forward), and 5′-TGCCTGGTATCCTGGCTAATATTCT-3′ (E09.9 reverse).

**Statistical analyses**

Results were expressed as the mean ± SEM. Statistical analysis was conducted using GraphPad Prism, version 5 (GraphPad Software, La Jolla, CA). The data were analyzed by the paired Student t test, pairing by experiment. Before testing, paired difference distributions were examined for outliers, which can indicate violation to the normality assumption of the t test. No outliers were apparent. Tests were performed between specific treatments and LPS treatments or between vitamin D treatment and control. Unpaired t test was used for comparison of responses between cells from wild-type and MKP-1−/− mice. Differences were considered significant at p < 0.05. A minimum of three independent experiments was conducted to allow for statistical comparisons.

**Results**

Pretreatment of human PBMC with vitamin D inhibits LPS-induced p38 phosphorylation in human monocytes

In this study, we examined the role of vitamin D in the regulation of LPS responses. Human PBMC were pretreated with vitamin D for 24 h, followed by stimulation with 10 ng/ml LPS. Both forms of the vitamin D, an active form, 1,25(OH)2D3, and 25(OH)D3, were tested. Monocytes/macrophages have previously been shown to be able to locally convert 25(OH)D3 into an active form (23). Vitamin D levels are normally measured by serum 25(OH)D3 levels, because this form of vitamin D is more stable, whereas the active form of vitamin D has a short half life (5). In these experiments, we assessed the anti-inflammatory effects of 25(OH)D3 doses that are related to vitamin D deficiency (15 ng/ml) and vitamin D
sufficiency (30 ng/ml, lower normal range; 50 and 70 ng/ml, upper normal range for the serum vitamin D levels) (1, 23, 24).

The binding of LPS to TLR4 on monocytes triggers immediate activation of MAPK, which together with activation of the canonical IKK pathway regulate NF-κB activation to induce pro-inflammatory cytokine production (25). We investigated whether the pretreatment of cells with vitamin D affects the activation of MAPK. The phosphorylation of three subfamilies of MAPK—ERK, JNK, and p38—was examined by flow cytometry. Human PBMC were pretreated with vitamin D for 24 h, followed by 10 min of treatment with 10 ng/ml LPS. After short-term stimulation with LPS, phosphorylation of p38 MAPK in CD14+ cells was induced. Monocytes cultured in media for 24 h had high level of p-JNK, which was not changed after LPS stimulation for 10 min. No ERK phosphorylation was observed 10 min after LPS treatment in these cells. As expected, LPS treatment did not activate CD3+ T cells.

As shown by flow cytometry (Fig. 1A), 6.5 ± 1.2% CD14+ cells expressed p-p38 MAPK (p-p38) prior to LPS treatment, and 23.6 ± 2.5% CD14+ cells expressed p-p38 after 10 min of LPS treatment (n = 4, p < 0.05). After LPS stimulation, a significant increase in the percentage of CD14+ cells that express p-p38 was observed; there was no change in p-p38 mean fluorescence intensity (Fig. 1C). It was found that 15 ng/ml 25(OH)D3, a concentration corresponding to the insufficient serum vitamin D levels in humans (24), did not suppress LPS-induced p38 phosphoryla-

**FIGURE 1.** Vitamin D inhibits LPS-induced p38 phosphorylation in human monocytes. PBMC were cultured in hormone-free medium containing 25(OH)D3 (A) or 1,25(OH)2D3 (B) for 24 h, followed by stimulation with 10 ng/ml LPS for 10 min. (A and B) As shown by flow cytometry, vitamin D pretreatment inhibits LPS-induced p38 phosphorylation in CD14+ cells (n = 4). (C) Representative flow cytometry data on the effects of LPS and vitamin D/LPS on p38 activation in human monocytes is shown. (D) Pretreatment with vitamin D significantly inhibits p-p38 expression by the cells as shown by Western blot. Whole-cell extracts from LPS or vitamin D/LPS-treated adherent PBMC fraction were prepared and blotted against p-p38 and total p38. (E) Fold changes in the densitometry of p-p38 normalized to total p38 MAPK expression are provided. Values represent mean ± SEM (n = 4 experiments).
tion (Fig. 1A), whereas significant inhibition of LPS-induced p38 phosphorylation was achieved with ≥30 ng/ml 25(OH)D$_3$ (Fig. 1A). Maximum inhibition was achieved with 50 ng/ml 25(OH)D$_3$ (a mean inhibition of 78% [n = 4; p < 0.01]). Similarly, a dose-dependent inhibition of LPS-induced p38 phosphorylation was observed in human monocytes when the cells were pretreated with active vitamin D (Fig. 1B, 1C). The maximum inhibitory effect was achieved when the cells were preincubated with 0.4 ng/ml (1 nM) 1,25(OH)$_2$D$_3$ (mean inhibition of 70% [n = 4; p < 0.01]). Inhibition of LPS-induced p38 phosphorylation by vitamin D was confirmed by Western blot analysis, because 10 nM 1,25(OH)$_2$D$_3$ significantly suppressed LPS-induced p38 phosphorylation by 75% in adherent fraction of the PBMC (n = 4; p < 0.01) (Fig. 1D, 1E). As confirmed by flow cytometry, this adherent fraction of PBMC consisted of 85–90% CD14$^+$ monocytes. Both flow cytometry and Western blot evaluations demonstrated that in vitamin D-pretreated cells, LPS-induced p-38 phosphorylation was inhibited to the level of p-p38 phosphorylation observed in cells cultured with media alone.

**Pretreatment with vitamin D inhibits LPS-induced IL-6 and TNF-α production by human monocytes**

Upon LPS stimulation, monocytes produce proinflammatory cytokines, such as TNF-α and IL-6 (26). Persistent inflammatory

![FIGURE 2](http://www.jimmunol.org/)

**FIGURE 2.** Vitamin D inhibits LPS-induced cytokine production in human monocytes. PBMC were cultured in hormone-free medium containing 25(OH)D$_3$ (A, C) or 1,25(OH)$_2$D$_3$ (B, D, E) for 24 h, followed by 24 h of treatment with 10 ng/ml LPS. IL-6 (A, B) and TNF-α (C, D) mRNA levels in the total PBMC were detected by real-time PCR after 24 h of stimulation with LPS (n = 4). IL-6 protein levels (E) in the culture supernatants following LPS stimulation were detected by ELISA (n = 4). (F) IL-6 expression in CD14$^+$ cells was detected in human monocytes by flow cytometry after 24 h of pretreatment with 10 nM 1,25(OH)$_2$D$_3$, followed by 6 h of stimulation with LPS. The percentage of CD14$^+$ cells expressing IL-6 was calculated. Values represent mean ± SEM (n = 4 experiments). (G) Representative flow cytometry data on the effects of LPS and vitamin D/LPS on IL-6 production by human monocytes are shown.
responses can damage host tissues (27, 28). To examine whether changes in LPS-induced p38 activation in the presence of vitamin D influenced cytokine production, human PBMC were pre-incubated as above with either 1,25(OH)2D3 or 25(OH)D3 for 24 h, followed by stimulation with 10 ng/ml LPS for 24 h. LPS treatment significantly induced IL-6 mRNA production by the cells \( (p < 0.05) \). When the cells were pre-incubated with \( \geq 30 \) ng/ml 25(OH)D3, a significant inhibition of LPS-induced IL-6 mRNA expression was observed \( (p < 0.01) \) (Fig. 2A). No inhibition of LPS-induced IL-6 expression was observed when the cells were cultured with \( 15 \) ng/ml 25(OH)D3 (Fig. 2A). All doses of the active form of vitamin D significantly inhibited LPS-induced IL-6 mRNA expression \( (p < 0.01) \) (Fig. 2B). The degree of suppression of IL-6 mRNA by 30 ng/ml \( (70 \) nM) 25(OH)D3 was comparable to the inhibition achieved with 0.04 ng/ml \((0.1 \) nM) of the active form of vitamin D \( (p < 0.01) \) (Fig. 2A, 2B). Similar vitamin D effects were observed in LPS-induced TNF-\( \alpha \) mRNA expression \( (p < 0.05) \) (Fig. 2C, 2D).

Upon stimulation with LPS, the amounts of IL-6 protein in culture supernatants increased from a basal level of \( 330 \pm 96 \) to \( 1385 \pm 277 \) pg/ml \( (p < 0.05) \). When the cells were pretreated with \( 10 \) nM 1,25(OH)2D3 for 24 h, LPS-induced IL-6 production by the cells was significantly inhibited by a mean of \( 77\% \) \( (n = 4; \ p < 0.01) \) (Fig. 2E). The inhibition of IL-6 production was more efficient with \( 10 \) nM 1,25(OH)2D3 as compared with \( 1 \) nM 1,25(OH)2D3 \( (p < 0.05) \) (Fig. 2E). These data were confirmed by flow cytometry as the amount of IL-6–producing monocytes was significantly increased after the stimulation with LPS from basal 0.8 \pm 0.4 to 29.7 \pm 4.9\% \( (n = 4; \ p < 0.01) \) (Fig. 2F, 2G). However, when the cells were pretreated with \( 10 \) nM 1,25(OH)2D3 for 24 h, the amount of IL-6–producing CD14+ cells induced by LPS was significantly inhibited by a mean of \( 67\% \) \( (n = 4; \ p < 0.05) \) (Fig. 2F, 2G).

**Vitamin D pretreatment induces MKP-1 expression**

MKP-1 plays a critical role in switching off p38 signaling and cytokine production in monocytes/macrophages after the inflammatory stimuli (18). Because vitamin D pretreatment significantly inhibited LPS-induced p38 phosphorylation, we examined whether this process was mediated via MKP-1 or other phosphatases. Pretreatment of human PBMC with \( 10 \) nM 1,25(OH)2D3 for 24 h resulted in significant increases in MKP-1 mRNA \( (2.5 \pm 0.1\text{-fold}; \ p < 0.05) \) (Fig. 3A) and protein \( (3.1 \pm 0.4\text{-fold}; \ p < 0.05) \) (Fig. 3C, 3D) expressions by the adherent PBMC fraction, which consisted mainly of monocytes. The expression of MKP-5, another phosphatase that has been reported to dephosphorylate p38, was not changed in adherent PBMC fraction after 24 h of culture with 1,25(OH)2D3 (Fig. 3B).

To examine the presence of potential VDRE sites in the human and murine MKP-1 promoter. A VDRE (labeled E4.7) sequence AGTTCAATCATCATA was located at \(-4708\) to \(-4694\) from the transcriptional start site of human MKP-1 gene. A VDRE (labeled E33) sequence AGTTCAATGGCTTACA was located at \(-33410\) to \(-33396\) from the transcriptional start site of murine MKP-1 gene. Underlined nucleotides directly interact with VDR. Several additional half VDRE sites were also found at the murine MKP-1 promoter, with the closest one with a sequence AGTTCA (labeled E0.9) located at \(-930\) to \(-925\) from the transcriptional start.

**FIGURE 3.** Vitamin D induces MKP-1 by human and mouse monocytes/macrophages. Human PBMC were cultured in hormone-free medium containing 10 nM 1,25(OH)2D3 or vehicle control for 24 h. An adherent PBMC fraction was collected. (A and B) Human MKP-1 and MKP-5 mRNA levels were tested by real-time PCR and normalized to \( \beta \)-actin mRNA levels \( (n = 6 \) experiments). (C) Human MKP-1 protein levels were tested by Western blot. (D) Fold changes in the densitometry of human MKP-1 to \( \beta \)-actin expression from Western blot are provided \( (n = 4 \) experiments). (E) Murine BMM cells were cultured in DMEM for 18 h and then treated with 10 nM 1,25(OH)2D3 or vehicle control for 6 h. mRNA levels of murine MKP-1 were tested and normalized to \( \beta \)-actin mRNA \( (n = 3 \) experiments). All values represent mean \( \pm \) SEM.
Vitamin D regulates MKP-1 expression. (FIGURE 4.) The recruitment of VDR to E4.7 and E0.9 VDRE sites of the murine MKP-1 promoter was tested by ChIP assays. We found that treatment of adherent PBMC with 10 nM 1,25(OH)2D3 for 24 h enhanced VDR binding and histone H4 acetylation by 2.4 ± 0.5-fold (p < 0.05) and 3.0 ± 0.8-fold (p < 0.05), respectively, at the E4.7 site of the human MKP-1 promoter (Fig. 4B, 4C). We found that treatment of murine BMM with 10 nM 1,25(OH)2D3 for 6 h enhanced VDR binding and histone H4 acetylation by 3.7 ± 0.4-fold (p < 0.05) and 6.26 ± 0.04-fold (p < 0.05), respectively, at the E33 site of the murine MKP-1 promoter (Fig. 4D, 4E). No increase in VDR binding and only a slight yet significant (p < 0.01) increase in histone H4 acetylation were observed at the E0.9 site (Fig. 4D, 4E). These data suggest that vitamin D-bound VDR interacts with the VDRE upstream of MKP-1 gene, thus, potentially influencing MKP-1 transcription.

Vitamin D inhibits LPS-induced p38 phosphorylation in macrophages derived from the bone marrow of the wild-type but not the MKP-1−/− mice

Next, we tested the ability of vitamin D to inhibit LPS-induced p38 phosphorylation in macrophages derived from the bone marrow of the wild-type and MKP-1−/− mice (29). Ten minutes of treatment with LPS resulted in a significant increase in p38 phosphorylation by 4.8 ± 0.2-fold (n = 3; p < 0.05) and 8.2 ± 0.2-fold (n = 3; p < 0.01) in wild-type and MKP-1−/− macrophages, respectively (Fig. 5A, 5B). As shown by Western blot analysis, pretreatment with 10 nM 1,25(OH)2D3 significantly inhibited LPS-induced p38 MAPK activation by a mean of 93% (n = 3; p < 0.05) in BMM from wild-type mice (Fig. 5B), but this inhibition was abolished in BMM from MKP1−/− mice (Fig. 5B).

Inhibition of LPS-induced production of IL-6 and TNF-α by vitamin D in mouse macrophages from wild-type mice by vitamin D was significantly compromised in MKP-1−/− mice

To examine whether inhibition of LPS-induced p38 activation by vitamin D in mouse macrophages influenced cytokine production, macrophages derived from the bone marrow of wild-type and MKP-1−/− mice were preincubated with either 10 nM 1,25(OH)2D3 or 75 nM (30 ng/ml) 25(OH)D3 for 24 h, followed by stimulation with 10 ng/ml LPS for 24 h. Significantly higher levels of IL-6 and TNF-α were observed in culture supernatants of the LPS-treated BMM from MKP-1−/− mice as compared with wild-type mice (p < 0.01 and p < 0.05, respectively). The amounts of LPS-induced IL-6 protein in culture supernatants were inhibited 67 and 61% by 1,25(OH)2D3 and 25(OH)D3, respectively, in wild-type macrophages. LPS-induced IL-6 production was inhibited only to 18 and 33%, respectively, in MKP-1−/− macrophages (Fig. 6A). Similarly, we observed that 1,25(OH)2D3 and 25(OH)D3 inhibited LPS-induced TNF-α protein in culture supernatants by 48 and 57%, respectively, in wild-type macrophages, whereas the inhibition of LPS-induced production of these cytokines was only 16 and 29%, respectively, in MKP-1−/− macrophages (Fig. 6B).

Discussion

In this study, we examined the effects of vitamin D at physiologic concentrations on LPS-stimulated inflammatory responses in monocytes/macrophages. We found that both 1,25(OH)2D3, an active form of vitamin D, and 25(OH)D3, which requires conversion by monocytes into an active form (23), dose dependently inhibited p38 phosphorylation and cytokines, IL-6 and TNF-α, and production in LPS-stimulated human monocytes. Upon vitamin D treatment, the expression of MKP-1 phosphatase mRNA and protein was significantly upregulated in both human monocytes and murine BMM. We demonstrated that vitamin D treat-
ment increased VDR binding to a putative VDRE in both human and murine MKP-1 promoter and enhanced histone H4 acetylation near this VDRE site. With macrophages derived from MKP-1 \(^2/2\) mice, we further demonstrated that vitamin D was no longer able to suppress LPS-induced p38 activation, followed by the compromised ability to inhibit LPS-induced IL-6 and TNF-\(\alpha\) production in the absence of MKP-1. Our current study therefore identified the upregulation of MKP-1 by physiologic concentrations of vitamin D as a novel pathway by which vitamin D inhibits LPS-induced p38 activation and cytokine production in monocytes/macrophages.

In recent years, vitamin D deficiency in humans has received significant attention (1, 24). According to the recent brief of the National Center for the Health Statistics in 2001–2006, 32% of the U.S. population had serum 25(OH)D \(_3\) levels, 20 ng/ml; 8% of the U.S. population had serum 25(OH)D \(_3\) levels, 12 ng/ml (30). Aside from its classical role as a modulator of calcium metabolism and bone health, vitamin D has been shown to have potent anti-inflammatory effects and consequently has been considered for adjunctive therapy for numerous chronic diseases including asthma, arthritis, and prostate cancer (4, 31, 32). A variety of pro- and anti-inflammatory effects for the vitamin D had been reported previously (33, 34). It has been shown that vitamin D can directly induce the production of the important antimicrobial peptides, cathelicidin and human \(\beta\) defensin 4, by human monocytes/macrophages and epithelial cells (23, 35). Antiproliferative and proapoptotic activity has been shown in vitamin D-treated tumor cells because of the induction of cyclin-dependent kinase inhibitors p21\(^{Waf/Cip1}\) and p27\(^{Kip1}\) and inhibition of c-Myc and anti-apoptotic Bcl-2 (32). Vitamin D had been demonstrated to suppress prostaglandin pathways in the tumor cell lines via inhibition of cyclooxygenase-2 production and stimulation of 15-hydroxyprostaglandin production by the cells (32). Vitamin D has also been shown to interfere with NF-\(\kappa\)B activation and signaling by increasing the expression of I\(\kappa\)B\(\alpha\) in the cells, thus interfering with the nuclear translocation of the activated NF-\(\kappa\)B subunits (36). It has also been reported that vitamin D can influence dendritic cells’ maturation and function (37). Several studies have highlighted the capacity of vitamin D to modulate the population and function of FOXP3\(^+\) and IL-10–producing T regulatory cells (37).

The current study found that human monocytes are capable of responding to treatment with two different forms of vitamin D: 1,25(OH)\(_2\)D\(_3\) and 25(OH)D \(_3\). 25(OH)D \(_3\) is converted into a functionally active form, 1,25(OH) \(_2\)D\(_3\), by the enzyme 25-hydroxyvitamin D-1\(\alpha\)-hydroxylase (CYP27b1), a process that primarily occurs in
kidneys (38, 39). However, it has been shown that monocytes, macrophages, and dendritic cells also express CYP27b1 (35, 40). Therefore, 1,25(OH)_{2}D_{3} can be produced locally and exert immunomodulatory effects (41). We demonstrated that 15 ng/ml 25(OH)_{2}D_{3} [a concentration amount considered in this study vitamin D deficiency (24)] did not suppress LPS-induced IL-6 and TNF-α production in human monocytes. We found that 25(OH)_{2}D_{3} at ≥30 ng/ml (levels considered vitamin D sufficient in humans) significantly inhibited IL-6 and TNF-α production induced by LPS. Furthermore, the degree of suppression of IL-6 and TNF-α production by 30 ng/ml 25(OH)_{2}D_{3} was comparable to the effects achieved by 0.04 ng/ml (0.1 nM) of the active form of the vitamin D. These data suggest that human monocytes have the ability to convert 25(OH)_{2}D_{3} to an active form. Furthermore, our study demonstrates that serum concentrations of 25(OH)_{2}D_{3} does matter for the optimal anti-inflammatory response of human monocytes, because the amount of the available circulating 25(OH)_{2}D_{3} influences local tissue concentrations of the active vitamin D (23, 35). These data support the idea that to achieve optimal anti-inflammatory effects by vitamin D it is important to maintain serum vitamin D levels > 30 ng/ml in the physiologic range (23, 42).

Dual-specificity phosphatases are a heterogeneous group of protein phosphatases that can dephosphorylate both phosphotyrosine and phosphothreonine residues within the same substrate. MKP-1 is the best-studied member of this family and is characterized for its role in the regulation of MAPK signaling cascades (43, 44). In this study, we demonstrated that vitamin D can up-regulate MKP-1 expression by monocytes/macrophages and use this pathway for the inhibition of the LPS-induced p38 phosphorylation. In this study, we focused on the early stages of monocyte activation by LPS to assess the contribution of vitamin D-regulated phosphatases on LPS-induced MAPK activation. We did not extend this assessment to 30 min post-LPS stimulation of avoid the effects of LPS-induced MKP-1 (18). Another member of the dual specificity phosphatase family, MKP-5, was recently shown to be induced by vitamin D treatment in normal prostate epithelial cells, resulting in inhibition of p38 activation in these cells (45). Vitamin D did not alter MKP-5 expression in human monocytes in our study.

Recently, it has been reported that vitamin D treatment down-regulates TLR2 and TLR4 expression by human monocytes and upregulates CD14 expression by these cells (46). The authors concluded that downregulation of TLR expression can substantially reduce LPS and lipoteichoic acid-mediated MAPK activation. MKP-1 expression under these conditions was not studied. Importantly, in this study, 100 nM active vitamin D was used. In our study, 10 nM active vitamin D was the highest dose used, and we did not observe changes in TLR4 protein expression by human monocytes in response to 24 h of pretreatment with the 10 nM active form of vitamin D (data not shown).

Vitamin D has been reported to regulate a variety of human and mouse genes through VDR-mediated VDRE binding (47, 48). Although VDRE have been well studied in genes such as CYP24A1 (48, 49), no VDRE has been discovered in MKP-1 gene to date. In this study, we identified a putative VDRE site ~4.7 kb upstream of transcriptional start site in the human MKP-1 promoter and a putative VDRE site ~33 kb upstream of transcriptional start site in the distal murine MKP-1 promoter. We confirmed VDR binding to these two sites using ChIP assays. The far upstream location of the putative VDRE in murine MKP-1 promoter is not surprising because genome-wide mapping of VDRE have indicated that VDREs are predominantly located in introns and intergenic intervals (7). Following the binding of VDR to VDRE, coactivators, corepressors, or mediator proteins may be recruited to the site depending on the effects of vitamin D on a specific gene transcription. Because vitamin D treatment significantly induces MKP-1 mRNA expression, it is likely that VDR binding to the MKP-1 promoter induces recruitment of the coactivators and initiates histone acetylation, leading to transcriptional activation (10). Our ChIP assays confirmed significantly enhanced histone H4 acetylation near the putative VDRE sites (E4.7 and E33) in humans and in the distal murine MKP-1 promoter, respectively, after vitamin D treatment.

Selective inhibitors for MKP-1 are currently unavailable, and inhibition of MKP-1 expression is difficult to accomplish via small interfering RNA in primary monocytes/macrophages. For these reasons, we explored the role of MKP-1 in vitamin D-mediated anti-inflammatory effects in monocytes by using BMM from MKP-1−/− mice and wild-type mice. Our data suggest that vitamin D regulation of MKP-1 is one of the essential pathways that inhibits LPS-induced cytokine production by monocytes/macrophages. We demonstrated that vitamin D-mediated suppression of the LPS-induced p38 phosphorylation was abolished, and the inhibition of LPS-induced production of IL-6 and TNF-α was significantly reduced in macrophages derived from MKP-1−/− mice. The fact that MKP-1 knockout did not completely abolish the vitamin D inhibition effect on LPS-induced cytokine production indicates that vitamin D engages additional pathways aside from MKP-1 to regulate LPS-induced proinflammatory cytokine production. This may include but not be limited to transrepression of NF-kB-mediated responses by VDR as reported previously (33, 36, 46). It was recently reported that LPS controls MKP-1 in activated macrophages via upregulation of the microRNA 101 (50). We did not find changes in microRNA 101 expression in vitamin D-pretreated human monocytes (E. Goleva, Y. Zhang, C. Hall, and D.Y.M. Leung, unpublished observations).

In summary, our study provides several novel discoveries: first, physiologic levels of vitamin D can modulate inflammatory activities, because 30–50 ng/ml 25(OH)_{2}D_{3} is sufficient to inhibit LPS-induced p38 activation and cytokine production in human monocytes (Figs. 1, 2). Second, the study identified the upregulation of MKP-1 by vitamin D as a novel mechanism by which vitamin D engages additional pathways aside from MKP-1 to regulate LPS-induced proinflammatory cytokine production. Finally, a putative VDR binding site was identified in the distal murine MKP-1 promoter and human MKP-1 promoter. Our current studies suggest that patients with chronic inflammatory diseases that are vitamin D deficient (<20 ng/ml) may benefit from oral supplementation of vitamin D to get their serum vitamin D level > 30 ng/ml.
