Neutrophil-Mediated Inhibition of Proinflammatory Cytokine Responses

Mark S. Gresnigt,* Leo A. B. Joosten,* Ineke Verschueren,* Jos W. M. van der Meer,* Mihai G. Netea,* Charles A. Dinarello,*+ and Frank L. van de Veerdonk*  

Neutrophils (polymorphonuclear neutrophils [PMNs]) play an elaborate role in the innate immune response against invading pathogens. Recent research provided evidence that PMNs can play a modulatory role in inflammation next to their primary role of phagocytosis. In the current study, we investigated whether neutrophils can modulate the innate immune response against Candida albicans. Production of the proinflammatory cytokines IL-1β and TNF-α by human PBMCs in response to C. albicans or LPS was decreased by coculture of PMNs; however, the anti-inflammatory cytokine IL-10 remained unaffected. Using Transwells and cells of patients with chronic granulomatous disease, we show that this downregulation of proinflammatory cytokine production was independent of phagocytosis and reactive oxygen species but was dependent on a soluble factor. We suggest that neutrophil-derived proteases are responsible for the downregulation of IL-1β and TNF-α, as cytokine production could be recovered by addition of α1-antitrypsin, an endogenous inhibitor of serine proteases. PMN lysates and neutrophil elastase could degrade recombinant human IL-1β and TNF-α but not IL-10, and this could be inhibited by addition of α1-antitrypsin. Moreover, we also provide evidence that the dampening effect of PMNs is present in vivo in a murine zymosan-induced arthritis model and a murine experimental endotoxemia model. Altogether, our data show that PMNs can dampen the proinflammatory response to C. albicans by protease-mediated degradation of cytokines. This observation suggests that PMNs might play a major regulatory role in the host defense against C. albicans and can be important for understanding the regulation of inflammation in general. The Journal of Immunology, 2012, 189: 4806–4815.

*Candida albicans* is a fungus that resides as a commensal on the mucosa of the oral cavity, genital tract, and gastrointestinal tract. Under normal conditions *Candida* is not pathogenic, but suppressed immunity or mucosal damage can lead to local or disseminated infections, the latter being associated with a high mortality (1). Neutrophils (polymorphonuclear neutrophils [PMNs]) play an important role in the host defense against *C. albicans*, and neutropenia poses a strong risk factor in the development of disseminated candidiasis (2, 3).

Neutrophils possess an effective armamentarium against invading microorganisms: they phagocytose invading pathogens and kill these using reactive oxygen species (ROS) and lysosomal enzymes (4). In addition, these cells have a more elaborate role in the innate defense against pathogens. Both in vitro and in vivo studies have shown that neutrophils are capable of Ag presentation by MHC class II complexes (5–7) and are able to express the costimulatory molecules CD80 and CD86 (8), which are relevant for induction of T cell proliferation (5, 7). Activated neutrophils have been shown to secrete cytokines such as IL-1, IL-1Ra, IL-6, IL-8, IL-12, IL-10, TNF-α, IFN-γ, and PGE2 (9–13). Moreover, proteases released by neutrophils can activate precursors of inflammatory cytokines such as pro–IL-1β (14–16) and a variety of receptors (17). Human leukocyte elastase activates TLR4, resulting in an upregulation of IL-8 (18), and triggers the epidermal growth factor receptor (19). Cathepsin G was shown to activate the formyl peptide receptor resulting in the recruitment of leukocytes (20).

Recently, we made the observation that neutrophils modulate cytokine production stimulated by bacterial peptidoglycans and LPS (21). As both neutrophils and proinflammatory cytokines are essential in host defense against *C. albicans*, we investigated whether neutrophils could also modulate cytokines produced by PBMCs after stimulation with *Candida.*

**Materials and Methods**

*Healthy volunteers and patients*  
Venous blood samples from healthy controls and patients were obtained after receipt of written informed consent. Four patients with autosomal chronic granulomatous disease (22) provided blood samples; all patients had homozygous mutations in the NCF1 gene (p47-phox), and defective ROS production was demonstrated.

**PBMC and PMN isolation**  
Venous blood was drawn into 10-ml EDTA tubes. PBMCs were isolated as previously described (23). Briefly, blood was diluted in PBS (1:1), and fractions were separated by Ficoll (Ficoll-Paque Plus; GE Healthcare, Zeist, The Netherlands) density gradient centrifugation. Cells were washed twice with PBS and resuspended in RPMI (RPMI 1640 Dutch modification supplemented with 10 μg/ml gentamicin, 10 mM l-glutamine, and 10 mM pyruvate) (Life Technologies, Invitrogen, Breda, The Netherlands). After density gradient centrifugation and removal of the PBMC fraction,
PMNs were isolated from the erythrocyte fraction by hypotonnic lysis. To remove erythrocytes, the cell suspension was treated with a hypotonnic lysis buffer (155 mM NH₄Cl, 10 mM KHCO₃) during 15-min incubation on ice. Subsequently, PMNs were harvested, washed twice in PBS, and resuspended in RPMI+. PBMCs and PMNs were counted using a particle counter (Beckmann Coulter, Woerden, The Netherlands), and the cell number was adjusted to 5 × 10⁶/ml and 1 × 10⁶/ml for PBMCs and PMNs, respectively. Giemsa staining on cytoplasm of the cell suspensions assessed purity of the cell populations. The PMNs contained >95% PMNs, and the PBMC fraction contained <5% PMNs. Viability of the PMNs was assessed by annexin-V and propidium iodide (PI) staining and revealed 1.35 ± 0.49% annexin-V+ PI+ cells (early apoptotic) and 0.50 ± 0.12% annexin-V– PI+ cells (necrotic). PMN lysates were prepared by three cycles of freeze-thawing to lyse the cells followed by centrifugation of 10 min at 12,000 × g to remove cell debris. 

**Stimuli and reagents**

*C. albicans* strain ATCC MYA-3573 (UC820) (24, 25) was used in all experiments and grown as previously described (24). In brief, Candida was shaken at 200 rpm overnight at 30°C in Sabouraud broth (1% mycological peptone and 4% glucose), transferred to fresh medium, and incubated for 4 h. The cells were harvested by centrifugation, and the pellets were washed twice in sterile PBS and resuspended to a density of 1 × 10⁷ cells/ml. Candida blastoconidia were heat-killed (HK) at 90°C for 1 h. LPS from *Escherichia coli* serotype O55:B5 was purchased from Sigma Chemical (St. Louis, MO), and repurified as previously described (26). Cytochalasin D was purchased from Biomed International (Antwerp, Belgium) and dissolved at a concentration of 5 mg/ml in DMSO. Cytochalasin D was used at a final concentration of 1 μg/ml and 10 μg/ml to deplete the mice. All primers were synthesized by Biologieq (Malden, The Netherlands). The PCR was performed with the Applied Biosystems 7300 real-time PCR system using PCR conditions 2 min at 50°C, 10 min at 95°C followed by 40 cycles at 95°C for 15 s and 60°C for 1 min. The mRNA levels of IL-1β and TNF-α were corrected for loading concentration differences using the signal of housekeeping protein β2M.

**Cytokine measurement**

Cytokines were measured using commercial available ELISAs (Sanquin, Amsterdam, The Netherlands, and R&D Systems) according to the protocol supplied by the manufacturer. IL-1β, TNF-α, and IL-10 were measured in culture supernatants from 24-h stimulations. Mouse IL-1β and TNF-α were measured by a radioimmunoassay.

**IL-1 bioassay**

NOB-1 cells are a murine cell line that responds to both human or mouse IL-1 by the production of IL-2; furthermore, these cells are unresponsive to other cytokines like TNF. Colony stimulating factors, IL-3, IL-5, IL-6, and IFN-γ used to deplete PMNs were plated in 96-well flat-bottom plates at a final density of 5 × 10⁶ cells/ml and were stimulated for 24 h with rHL-1β that was exposed to medium, PMN lysates, or NE in presence or absence of α-antitrypsin (as described earlier). After 24 h of incubation at 37°C, 5% CO₂, the culture supernatants of the NOB-1 cells were collected, and IL-2 production by the NOB-1 cells was measured by ELISA (R&D Systems).

**Proteoglycan synthesis in PMN-depleted mice**

Sexually mature female C57Bl/6 mice (8–12 wk old, weights 20–25 g) were used. The animals were kept under routine laboratory conditions (21–22°C, relative humidity 60%, and a 12-h light-dark cycle), fed a standard commercial pellet diet (RHM, Hope Farms, The Netherlands), and given acidified tap water ad libitum.

The mice were irradiated with 7.5 Gy 4 d prior to the experiment to deplete the mice of PMNs. The protocol for depletion of neutrophils was highly effective, more than 98% of all neutrophils were depleted when the PMNs were measured in the bloodstream. To induce arthritis, 180 μg zymosan (Sigma, St. Louis, MO) in PBS was injected intra-articularly in day 0 into the right knee whereas the left contralateral joint received an equal volume of PBS. The mice were killed by cervical dislocation, and whole patellae were dissected from the right artithic and left control knee joints, leaving the cartilage fully intact. The patellae were isolated 2 d after the intra-articular injection of zymosan from the knee joints with minimal amount of surrounding tissue. The fully intact cartilage was incubated in RPMI 1640 medium with 1-8 MBq [³¹S]sulfate (Na₂⁶³⁵SO₄; Du Pont, ‘s-Hertogenbosch, The Netherlands) for 3 h at 37°C and then washed three times in physiological saline to remove non-incorporated radiolabel. Patellae were then fixed in 40% buffered formaldehyde and decalcified in 5% formic acid for 3 h and the patellar cartilage removed from the surrounding tissue and digested in Lumasolve (Lumac, Landgraaf, The Netherlands) at 60°C. The quantity of radioactive sulfate incorporated was assayed by liquid scintillation counting (30).

**Endotoxemia model in PMN-depleted mice**

Sexually mature female C57Bl/6 mice (8–12 wk old, weights 20–25 g) were used. The animals were kept under routine laboratory conditions (21–22°C, relative humidity 60%, and a 12-h light-dark cycle), fed a standard commercial pellet diet (RHM, Hope Farms, The Netherlands), and given acidified tap water ad libitum.

The mice were injected i.p. with rat anti-mouse GR1 or isotype control (100 μg in 200 μl PBS) (eBioscience) 4 d prior to the experiment to deplete the mice of PMNs. On day 0, the mice were injected i.p. with 100 μg/ml *E. coli* LPS. After 2 h, the mice were anesthetized with isoflurane, and blood samples were obtained in 1-ml EDTA tubes for measurement of IL-1β and TNF-α in the plasma. Subsequently, the mice were killed by cervical dislocation. Spleens were harvested, homogenized, and the cell number of suspensions adjusted to 1 × 10⁶/ml. The cell suspensions (500 μl/well) were plated in 24-well plates (Corning) and incubated for 48 h at 37°C and 5% CO₂. IL-1β and TNF-α were measured by radioimmunoassay in culture supernatants and EDTA plasma.
Statistical analysis

The differences between cytokine concentrations in PBMCs alone and with or without PMN or PMN lysate cocultures were analyzed with the Wilcoxon signed rank test. For comparisons between multiple conditions, the Friedman test and the Wilcoxon signed rank test with Bonferroni correction for multiple testing as posttest were used. Differences between mouse groups were analyzed using the Mann–Whitney U test. A p value < 0.05 was considered statistically significant. All experiments were performed at least twice, the data represent cumulative results of all experiments performed, and the number of donors is given as n in all figure legends. The data are presented as mean ± SEM unless otherwise indicated. Data were analyzed using GraphPad Prism v5.0.

Results

PMNs modulate cytokine production induced by C. albicans

To investigate the role of PMNs on the innate immune response against C. albicans, PBMCs were exposed to C. albicans blastoconidia either alone or in coculture with PMNs. IL-1β, TNF-α, and IL-10 production of either unstimulated PBMCs, unstimulated PMNs, or PMNs stimulated with C. albicans or LPS was below the detection limit of the assays (data not shown). IL-1β and TNF-α production by PBMCs incubated with C. albicans was significantly reduced when the cells were cocultured with PMNs; IL-10 production remained unaffected under these conditions (Fig. 1A). To rule out the possibility of competition between PMNs and PBMCs in phagocytosis of Candida, we used LPS as a non-phagocytosed stimulus. Similarly to Candida stimulation, LPS-induced IL-1β and TNF-α production by PBMCs was lowered in the presence of PMNs (Fig. 1B) (21). To investigate whether the decreased cytokine concentration could be explained by internalization of the cytokine in the cell or by binding of the cytokine to membrane-bound receptors, we measured the concentration of TNF in the cells lysed in Triton-X, which represents the concentration of intracellular and membrane-bound TNF. The total concentration of intracellular and membrane-bound TNF-α was also reduced after coculture with PMNs (Fig. 1C).

To explore further whether phagocytosis of C. albicans by PMNs plays a role in the decreased cytokine production, we repeated the experiments in the presence of cytochalasin D, an inhibitor of actin filament polymerization, to block phagocytosis and to block internalization of receptors (31). The addition of cytochalasin D resulted in a decreased IL-1β production by PBMCs stimulated with C. albicans, and coculture of PMNs could further reduce the cytokine production to undetectable levels in the presence of cytochalasin D (Fig. 1D).

**FIGURE 1.** PMNs modulate cytokine production induced by C. albicans and LPS. (A) IL-1β, TNF-α, and IL-10 in culture supernatants of human PBMCs (2 × 10^6/ml) that were stimulated with HK C. albicans blastoconidia (2 × 10^6/ml) either alone or in coculture with PMNs (2 × 10^6/ml) (n = 21). (B) A similar stimulation was performed with E. coli LPS (10 ng/ml) (n = 7). (C) Membrane-bound and intracellular TNF-α in/on human PBMCs (2 × 10^6/ml) that were stimulated with HK C. albicans blastoconidia (2 × 10^6/ml) either alone or in coculture with PMNs (2 × 10^6/ml) (n = 6). (D) Cytochalasin D (1 μg/ml) was used to block phagocytosis and receptor internalization in PBMCs (2 × 10^6/ml) stimulated with 2 × 10^6/ml HK C. albicans blastoconidia with or without 2 × 10^6/ml PMNs (n = 6). (E) To supplement the culture with additional nutrients, 10% human serum was added to 2 × 10^6/ml PBMCs stimulated with 2 × 10^6/ml HK C. albicans blastoconidia with or without presence of 2 × 10^6/ml PMNs, and IL-1β was measured (n = 6). (F) PBMCs (2 × 10^6/ml) were stimulated with HK C. albicans blastoconidia either alone (black bar) or with a Transwell (TW) containing a similar amount of PBMCs (white and hatched bars). The PBMCs in the Transwell were either unstimulated (white bar) or stimulated with HK C. albicans (hatched bar). After 24 h, IL-1β was measured by ELISA (n = 2). *p < 0.05, ***p < 0.001.
The observed modulation of cytokine production with PMN coculture could also be due to the presence of increased cell numbers, resulting in decreased nutrients in the culture medium. Therefore, we supplemented the cultures with 10% human serum as a source of nutrients; the lowered IL-1β production with PMN coculture was still present (Fig. 1E). In addition, we performed similar experiments with a double concentration of PBMCs (4 × 10⁶/ml) in the same volume to match the concentration of cells in the PBMC–PMN coculture and tested whether nutritional depletion due to an increased amount of cells was responsible for the observed effects. We did not observe decreased proinflammatory cytokine production in these experiments (data not shown). Furthermore, there was no significant elevation of lactate dehydrogenase levels in the cocultures with PMNs (data not shown), and microscopic examination with trypan blue showed >95% cell survival after 24 h. No free hemoglobin could be detected in the cultures, indicating that the washing steps after erythrocyte lysis were adequate to remove the contents of lysed erythrocytes (data not shown). These observations strongly suggest that the observed inhibition of IL-1β and TNF-α production is not caused by cell death of neutrophils or free hemoglobin.

Modulation of cytokine production by a soluble factor released from PMNs

We used a Transwell system to investigate whether the modulation of Candida-induced proinflammatory cytokines by PMNs would rely on direct contact between PMNs and PBMCs. PBMCs stimulated with HK C. albicans were cocultured with PMNs that were separated by a Transwell membrane with an 0.40-μm pore diameter. Coculture with Candida-stimulated PMNs or unstimulated PMNs in Transwells significantly decreased the IL-1β and TNF-α production by PBMCs present in the well below, whereas IL-10 production remained unaffected. When, instead of PMNs, PBMCs were placed in the Transwell, Candida-induced IL-1β production by PBMCs was not reduced (Fig. 1F).

These experiments show that the modulation can be present independent of direct contact and suggests that the modulation can be induced by a soluble factor specifically released by PMNs. Therefore, we investigated whether PMN lysate, after removal of cellular debris by centrifugation, was able to decrease proinflammatory cytokine production by PBMC stimulated with C. albicans. The PMN lysates inhibited both IL-1β and TNF-α production but not IL-10 production (Fig. 2B). In contrast, lysates of PBMCs did not show this effect; they rather showed an increase of TNF-α and IL-10 production, although this was not significant (Fig. 2C). However, it must be noted that the reduction of IL-1β and TNF-α concentrations when PMNs were not separated from the PBMCs was significantly more prominent (Fig. 2A), suggesting that in addition to a soluble factor, a contact-dependent mechanism can contribute to the inhibition of proinflammatory cytokine responses.

Influence of PMNs on transcription of proinflammatory cytokines

We investigated whether the modulation of proinflammatory cytokines by PMNs is at the level of transcription. PBMCs were stimulated with HK C. albicans alone or in coculture with PMNs or PMN lysate. IL-1β and TNF-α mRNA levels were similar between culture with PBMCs alone and addition of PMNs (Supplemental Fig. 1A, 1B). IL-1β mRNA expression was also unchanged upon addition of PMN lysate, whereas TNF-α mRNA expression significantly decreased in the presence of PMN lysate (Supplemental Fig. 1A, 1B).

Modulation of cytokine production by PMNs is dependent on proteases

After the observation that the modulation of IL-1β and TNF-α by coculture of PMNs is likely to be dependent on a soluble factor,

![Figure 2](http://www.jimmunol.org/)

**FIGURE 2.** Modulation of cytokine production by a soluble factor released from PMNs. (A) Human PBMCs (2 × 10⁶/ml) were stimulated with 2 × 10⁶/ml HK C. albicans blastoconidia with and without the presence of 2 × 10⁶/ml PMNs either in direct coculture (white bar) or in coculture separated by an 0.4-μm Transwell (TW white and hatched bars). PMNs in the Transwell were either unstimulated (TW, white bar) or stimulated with 2 × 10⁶/ml HK C. albicans (TW, hatched bar); after 24 h of incubation, ELISA measured the production of IL-1β, TNF-α, and IL-10 (n = 7). (B) Human PBMCs (2 × 10⁶/ml) were stimulated with 2 × 10⁶/ml HK C. albicans in the presence or absence of PMN lysate; after 24 h of incubation, IL-1β production was measured (n = 8). (C) Similarly, 2 × 10⁶/ml PBMCs were stimulated with 2 × 10⁶/ml HK C. albicans in the presence or absence of PBMC lysate; after 24 h of incubation, IL-1β production was measured (n = 4). *p < 0.05, **p < 0.01.
the possible contents of PMNs that could be responsible for the observed effect were systematically addressed. PMNs contain NADPH-oxidase to generate ROS. Others and we have previously demonstrated that ROS can dampen the production of IL-1β by PBMCs (22, 32, 33), therefore we investigated whether the release of ROS by PMNs was involved in the modulation of proinflammatory cytokine production by PBMCs. To test this hypothesis, we used PMNs isolated from patients with chronic granulomatous disease, who have a defect in NADPH oxidase and therefore are not able to produce measurable amounts of ROS (34). PMNs from these patients showed a similar capacity to decrease the production of IL-1β and TNF-α by PBMCs (Fig. 3A).

Role of NE in the modulation of cytokine production by PMNs

NE is a protease that is present in the granula of neutrophils. Similar to PMNs, the addition of NE to PBMC cultures significantly reduced Candida-induced IL-1β and TNF-α production (Fig. 4A). This effect of NE was reduced in the presence of α1-antitrypsin (Fig. 4A), and in the presence of the specific elastase inhibitor MeOSuc-AAPV-CMK (Fig. 4B). To elucidate the magnitude of the role of NE in PMN-mediated degradation of IL-1β and TNF-α, we added MeOSuc-AAPV-CMK to PBMC–PMN cocultures. Addition of this inhibitor resulted in partial restoration of the IL-1β levels, but TNF-α levels were not affected (Fig. 4C).

PMNs and NE degrade IL-1β and TNF-α but not IL-10

To determine whether the reduced cytokine levels were the effect of degradation by proteases such as NE, we incubated rhIL-1β, rhTNF-α, and rhIL-10 with PMN lysate or NE. After an incubation of 24 h, PMN lysate resulted in a reduced recovery of both rhIL-1β and rhTNF-α (Fig. 5A). Similarly, NE reduced the recovery of rhIL-1β and rhTNF-α (Fig. 5B). Both the degradation of rhIL-1β and rhTNF-α by PMN lysates and NE could be inhibited in the presence of α1-antitrypsin. In contrast, levels of rhIL-10 did not decrease by addition of either PMN lysate or NE (Fig. 5A, 5B). The use of intact PMNs instead of NE or PMN lysates yielded similar results (data not shown). Using the NOB-1 IL-1
bioassay, we determined whether the IL-1\(\beta\) concentrations that were decreased due to the degradation by proteases also results in reduced biological activity of IL-1\(\beta\). We found that with proteolytic degradation by either PMN lysates or NE, the biological activity of IL-1 is also reduced (Fig. 5C).

Depletion of neutrophils aggravates zymosan-induced arthritis

To investigate whether our in vitro finding that neutrophils reduce proinflammatory cytokine responses also applies to in vivo circumstances, we tested the modulatory role of neutrophils on proinflammatory cytokine production in a zymosan-induced arthritis model. This model was chosen because PMNs are known to play a large role in arthritis, and the loss of proteoglycan synthesis, which is dependent on proinflammatory cytokines and especially IL-1, represents readout for arthritis severity in this model (36). To deplete PMNs, C57Bl6 mice were injected with anti-GR1 Abs to deplete PMNs or isotype control. Four days later, mice were injected i.p. with LPS or saline, and after 2 h, circulating levels of IL-1\(\beta\) and TNF-\(\alpha\) were determined.

We also investigated the capacity of the spleens to produce IL-1\(\beta\) and TNF-\(\alpha\) in response to the injected LPS. To investigate whether the PMN depletion was successful, peripheral blood was Giemsa stained and microscopically analyzed. Mice that received anti-GR1s showed 90% (SD 6 5%) depletion of circulating PMNs (Fig. 7A). Two hours after injection of LPS, the PMN-depleted mice demonstrated significantly higher IL-1\(\beta\) plasma concentrations than non-PMN-depleted mice. Plasma TNF-\(\alpha\) was also increased, yet not significantly (Fig. 7B). IL-1\(\beta\) and TNF-\(\alpha\) concentrations were below the detection limit in saline-injected mice. The spleen homogenates isolated from the mice that received LPS demonstrated higher concentrations of IL-1\(\beta\) and TNF-\(\alpha\) induc-

**FIGURE 5.** Modulation of cytokine production is the result of degradation. (A and B) Different concentrations of rhIL-1\(\beta\) (500 pg/ml to 16 pg/ml), rhTNF-\(\alpha\) (1000 pg/ml to 31 pg/ml), and rhIL-10 (300 pg/ml to 1 pg/ml) were incubated for 24 h without any addition or with addition of PMN lysate (A) or NE (B) in the presence or absence of \(\alpha\)-antitrypsin (AAT) to inhibit protease activity. After incubation, the amount of degradation was determined by the detection of these cytokines by ELISA. Values are plotted as mean ± SD of two separate experiments in duplicate. (C) IL-1 bioactivity, determined by IL-2 production of NOB cells, of rhIL-1 (1000 pg/ml) that was exposed to medium, PMN lysate, or NE in the presence or absence of \(\alpha\)-antitrypsin (1 mg/ml). **p < 0.01.
tion in PMN-depleted mice compared with non-PMN-depleted mice (Fig. 7C). Spleen homogenates of mice that were injected with saline did not show any ex vivo cytokine production (data not shown).

Discussion

In the current study, we demonstrate that PMNs are able to downregulate the proinflammatory cytokine production of human monocytes induced by *C. albicans* and *E. coli* LPS, whereas the anti-inflammatory cytokine IL-10 remains unaffected. This effect was independent of phagocytosis and the production or release of ROS by neutrophils. It was due to a soluble factor released from neutrophils, and α1-antitrypsin reduced the inhibitory effects of neutrophils suggesting that proteases from neutrophils are responsible for the modulatory effects of PMNs. Elastase, a main serine protease present in the granules of neutrophils, was found to be partially responsible for the observed effects. Furthermore, we show that IL-1β and TNF-α levels can be degraded by elastase and neutrophil-derived proteases in PMN lysates. Thus, neutrophils are able to dampen proinflammatory cytokine production from mononuclear cells by the release of proteases, without an effect on the anti-inflammatory cytokine IL-10. We observed in two murine models—a zymosan-induced arthritis model and an endotoxemia model—that the absence of PMNs in vivo results in aggravated arthritis and in increased cytokine levels, suggesting that the neutrophil can play a role in reducing the proinflammatory response both in vitro and in vivo.

Because the neutrophil is generally viewed as a proinflammatory cell, our finding that proinflammatory cytokine production of PBMCs in response to *Candida* in the presence of PMNs is decreased is rather unanticipated. Neutrophils are primarily phagocytes. Therefore, we investigated the possibility that phagocytosis of *Candida* itself resulting in lower exposure of PBMCs to *Candida* played a role. By exposing the cells to LPS, a molecule that is not phagocytosed, and by inhibiting phagocytosis with cytochalasin D, we were able demonstrate that the inhibition of proinflammatory cytokine production was not dependent on phagocytosis. It has also been demonstrated that PMNs are able to sequester cytokines (37). Arguing against sequestrations of cytokines as a plausible explanation for our findings is that the concentration of intracellular and membrane-bound TNF-α was also decreased in the presence of PMNs, and blocking internalization of cytokine receptors did not affect the inhibition of cytokine concentrations by PMNs. Furthermore, the observation that lysates of neutrophils and cocultures of PMNs in the Transwell experiments also result in a decrease of...
proinflammatory cytokine production supports the conclusion that a soluble factor released by PMNs contributes to the reduction of proinflammatory cytokine concentrations.

Reduction of proinflammatory cytokines by PMNs in the Transwell system was not as strong as that by PMNs in direct contact. It could be possible that the closer proximity of the PMNs that produce the inhibiting proteases to the monocytes producing IL-1β and TNF-α resulted in a relatively higher concentration of the inhibitors at the site of cytokine production. Still, the stronger inhibition in direct contact could also point to a secondary, contact-dependent mechanism responsible for downregulation of proinflammatory cytokines by PMNs. Apoptotic neutrophils were found to regulate IL-12p40 IL-6 production by IFN-γ-stimulated murine macrophages (38). Neutrophils are most likely entering the early apoptotic phase during 24-h experiments, and therefore this could contribute to the dampening of the proinflammatory cytokine response as suggested by the literature. This might also be an additional explanation why the reduction by PMNs in direct contact is more evident than that in Transwells.

Neutrophils generate large amounts of NADPH-dependent ROS, which have previously been demonstrated to have the ability to inhibit IL-1β production (22, 32, 33). However, PMNs from patients with defective NADPH oxidase were still able to reduce cytokine production similarly to controls, suggesting that ROS is not the soluble factor that is responsible for the inhibitory effect of PMNs on proinflammatory cytokines. Notably, the presence of α1-antitrypsin resulted in a recovery of cytokine production. α1-Antitrypsin is most effective in neutralizing NE compared with all other neutrophil-derived serine proteases (39). We were able to demonstrate that NE itself reduces IL-1β and TNF-α production, and a specific NE inhibitor could restore the inhibitory effect of NE on the production of proinflammatory cytokines by PBMCs. Notably, in the cocultures of PBMCs with PMNs, the effect was most prominent on the production of IL-1β. These observations suggest that NE plays a role in the inhibitory effects of PMNs on proinflammatory cytokines produced by PBMCs; however, proteases other than NE that are inhibited by α1-antitrypsin are probably also involved. In addition, it must be noted that the recovery by α1-antitrypsin was partial. This can be explained by the fact that α1-antitrypsin is a reversible inhibitor, or that α1-antitrypsin is sequestered by the PBMCs. However, in the degradation assays, the recovery by α1-antitrypsin was almost complete, suggesting a significant role for proteases in the degradation of proinflammatory cytokines.

To elucidate the mechanism through which proteases such as NE modulate cytokine production, we first determined whether modulation was exerted proximally at the level of receptor-induced signaling and/or gene transcription. Notably, transcription of IL-1β and TNF-α in the presence of PMN was not affected. Although we found an effect on transcription of TNF-α with lysates of PMNs, this was not observed when PBMCs were cultured in the presence of intact PMNs. We hypothesized that the effects must therefore be exerted posttranscriptionally, or at the level of processing. Using recombinant cytokines, we show that NE and lysates from neutrophils can exert their effects by cleaving IL-1β and TNF-α extracellularly and can reduce IL-1 bioactivity while leaving IL-10 unaffected. The observation that the degradation of proinflammatory cytokines was completely inhibited by addition of α1-antitrypsin suggests that proteases are responsible for the lower concentrations of IL-1β and TNF.

These observations are in line with recent studies reporting that neutrophil serine proteases have a regulatory role during inflammation (40). The degradation of TNF-α by neutrophil-derived proteases is supported by various studies describing that neutrophil-derived proteases, and especially NE, in high concentrations can inactivate TNF-α (41–44). Furthermore, it was shown that pancreatic proteases in a model of acute pancreatitis are also able to inactivate TNF-α (45), and proteinase 3 was found to release membrane-bound TNF-α from alveolar macrophages (46). As an indirect mechanism, NE, cathepsin G, and proteinase 3 (PR3) can degrade CD14 on monocytes, which results in decreased TNF-α levels after stimulation with LPS (47–49). Notably, there are also reports that suggest a proinflammatory role for neutrophil-derived proteases. The release of membrane-bound TNF-α is promoted by PR3, NE, and cathepsin G (14, 15, 44). Furthermore, caspase-1-independent activation of pro–IL-1β can be mediated by NE and PR3 (14–16, 50). These findings suggest that proteases released by neutrophils can have proinflammatory as well as anti-inflammatory properties.

To see whether the inhibitory role of PMNs has in vivo relevance, we studied the effect of PMN depletion in a local and a systemic murine inflammatory model: zymosan-induced arthritis and endotoxemia, respectively. We observed a significant stronger reduction in proteoglycan synthesis when PMNs were depleted. Because the reduction of proteoglycan synthesis by zymosan is highly dependent on IL-1, this observation is in line with the hypothesis that the presence of PMNs during inflammation results in a lower proinflammatory cytokine production and that in the absence of PMNs, there is more proinflammatory cytokine production (36). In addition, the absence of PMNs during endotoxemia resulted in increased proinflammatory cytokine concentrations in serum and in the spleen. Several reports are in line with our findings, Wound fluids from neutropenic mice were found to contain increased levels of the proinflammatory cytokines IL-6 and TNF-α, but IL-10 was unaffected in their model (51). However, this study suggested that the responsible factor was a molecule of <3000 Da, which is smaller than common PMN-derived proteases. In a previous study, we have shown increased TNF-α and IL-1 levels after LPS challenge in neutropenic mice, which could partly be attributed to increased uric acid levels (52). Moreover, another study demonstrated that coculture of PMNs with PBMCs reduced only TNF-α but not IL-1β in response to LPS (53), albeit 25- to 100-fold more LPS was used in this particular study.

The downregulation of IL-1β and TNF-α production by neutrophils in vitro and in vivo may lead to new insights in highly relevant mechanisms, such as the control of inflammatory responses, endotoxin tolerance, and fever in neutropenic patients. Prolonged neutropenia, either primary or that associated with the treatment of hematological disorders, is often accompanied by fever. Patients with neutropenia and fever were shown to have increased plasma levels of IL-1β and TNF-α despite the absence of bacteremia (54). Therefore, it could be possible that the absence of PMNs results in an inability to dampen proinflammatory cytokine production like IL-1, which results in fever. In human experimental endotoxemia, exposure to bacterial endotoxin (LPS) leads to hyporesponsiveness to a new endotoxin challenge (55). It has been described that reduced TNF-α production plays a major role in endotoxin tolerance. Our observation that PMNs are able to downregulate responses to LPS both in vitro and in vivo could potentially be a mechanism of acute endotoxin tolerance. This is partially supported by the observation that a functional hetero- geneic neutrophil population, accompanied by reduced proinflammatory cytokine production, can be observed after LPS challenge (56). It is currently under investigation whether these mechanisms are similar.

In conclusion, we demonstrate that PMNs are capable of downregulating innate immune responses to C. albicans and LPS in vitro by the release of proteases that have the ability to degrade the proinflammatory cytokines IL-1β and TNF-α, while IL-10 is

Supplemental Figure 1. Influence of PMNs on transcription of pro-inflammatory cytokines

Following stimulation of PBMCs (2x10^6/ml) with *Candida* (2x10^6/ml), mRNA was isolated, reverse transcribed and IL-1β (a) and TNF-α (b) cDNA was measured by qPCR. The mRNA levels from human PBMCs alone were compared with co-culture with 2x10^6/ml PMNs (left panels) (n=8) or addition of PMN lysate (right panels) (n=8) mRNA of unstimulated cells was set at 1.
