Availability of 25-Hydroxyvitamin D3 to APCs Controls the Balance between Regulatory and Inflammatory T Cell Responses

Louisa E. Jeffery,* Alice M. Wood,† Omar S. Qureshi,* Tie Zheng Hou,* David Gardner,* Zoe Briggs,* Satdip Kaur,* Karim Raza,***‡ and David M. Sansom*

1,25-Dihydroxyvitamin D3 [1,25(OH)2D3], the active form of vitamin D, exerts potent effects on several tissues including cells of the immune system, where it affects T cell activation, differentiation and migration. The circulating, inactive form of vitamin D, 25(OH)D3, is generally used as an indication of vitamin D status. However, use of this precursor depends on its uptake by cells and subsequent conversion by the enzyme 25(OH)D3-1α-hydroxylase (CYP27B1) into active 1,25(OH)2D3. Using human T cells, we show in this study that addition of inactive 25(OH)D3 is sufficient to alter T cell responses only when dendritic cells (DCs) are restricting the availability of inactive 25(OH)D3 to DC. These data indicate that the level of free 25(OH)D3 available to DCs acts as a carrier to enhance the use of vitamin D. However, we show that vitamin D binding protein modulates T cell responses by restricting the availability of inactive 25(OH)D3 to DC. These data indicate that the level of free 25(OH)D3 available to DCs determines the inflammatory/regulatory balance of ensuing T cell responses. The Journal of Immunology, 2012, 189: 5155–5164.

Besides its longstanding association with calcium regulation and bone density, more widespread physiological roles for vitamin D are now acknowledged. This is consistent with the broad distribution of the vitamin D receptor (VDR) throughout the body (1) and the association of low vitamin D status with numerous diseases in epidemiological studies (2). Interestingly, low vitamin D appears to increase the risk of immune-related diseases, including multiple sclerosis (3, 4), rheumatoid arthritis (RA) (5), type 1 diabetes (6), and inflammatory bowel disease (7). Thus, vitamin D appears to have an important immune-regulatory function, which may have implications for the treatment of many conditions. Consistent with this, vitamin D supplementation in mouse models of autoimmunity has been demonstrated to have prophylactic and therapeutic benefit (8–13). In vitro studies have also identified profound immunological effects of 1,25-dihydroxyvitamin D3 (1,25(OH)2D3), the biologically active form of vitamin D, including inhibited maturation of APCs, which involves downregulation of MHC and costimulatory molecules (14–16). In addition, we and others (17–21) have shown that 1,25(OH)2D3 can act directly upon CD4+ T cells, suppressing cytokines such as IFN-γ, IL-17, IL-21, and IL-22, while enhancing the regulatory markers FOXP3, CTLA-4, and IL-10. Although these findings demonstrate the ability of active 1,25(OH)2D3 to directly regulate T cell responses, tight homeostatic mechanisms operate in vivo to maintain serum 1,25(OH)2D3 at ~0.1 nM (2), which is somewhat below the effective concentration of 1,25(OH)2D3 seen in in vitro studies. It is therefore likely that the level of 1,25(OH)2D3 circulating systemically is insufficient to promote anti-inflammatory effects in vivo. Furthermore, serum 1,25(OH)2D3 concentration does not tend to vary greatly between individuals, in which even those regarded vitamin D deficient can show relatively normal 1,25(OH)2D3 levels (2). Thus, local production of active 1,25(OH)2D3 from its inactive precursor is likely to be important in order for vitamin D to contribute to immune regulation in vivo.

Generation of active vitamin D from its inactive precursor, 25(OH)D3, which is the predominant form of vitamin D in the circulation, is carried out by the mitochondrial cytochrome P450 enzyme 25(OH)D3-1α-hydroxylase (CYP27B1). Although most is known about the activity of this enzyme in the kidneys and bone, wider expression of CYP27B1 is observed (22, 23), including its expression by macrophages and dendritic cells (DCs) (24). Indeed, high levels of 1,25(OH)2D3 are found in patients with sarcoidosis resulting from CYP27B1 activity in disease-associated macrophages (25). Although the ability of DCs and macrophages to convert 25(OH)D3 to 1,25(OH)2D3 is clear, whether sufficient 1,25(OH)2D3 is generated to subsequently affect T cell function is not known. Furthermore, other factors in serum influence the bioavailability of both 25(OH)D3 and 1,25(OH)2D3 to immune cells. In this respect, vitamin D binding protein (DBP) is of particular interest, because the majority of 25(OH)D3 and 1,25(OH)2D3 is transported by this protein in serum. Indeed, DBP can facilitate uptake of 25(OH)D3 by epithelial cells of the kidney proximal tubule (26), mammary cells (27), and osteoblasts (28) that express the DBP transporter proteins megalin and cubulin. However, the impact of DBP on 25(OH)D3 uptake by immune cells is less clear.
Furthermore, the DBP gene is polymorphic, and three common variants termed GC1S, GC1F, and GC2 are found that appear to have different functional properties, including varying binding affinities for vitamin D (29, 30). Interestingly, DBP polymorphisms have also shown association with inflammatory disorders, including chronic obstructive pulmonary disease (COPD), tuberculosis, Graves’ disease, RA, and diabetes (31–33). Thus, 25(OH)D₃ status as well as DBP genotype and serum DBP concentration might modulate immune responses.

We have therefore investigated the effect of local conversion of inactive 25(OH)D₃ to active 1,25(OH)₂D₃ by DCs on subsequent T cell responses. We observed that 1,25(OH)₂D₃ was readily produced by DCs upon maturation at a level sufficient to promote an anti-inflammatory T cell phenotype, exemplified by high CTLA-4 and decreased expression of IL-17, IFN-γ, and IL-21. In contrast, T cells alone used 25(OH)D₃ poorly, consistent with their limited expression of CYP27B1. The magnitude of the effect resulting from DC conversion of 25(OH)D₃ was dependent on the concentration of available 25(OH)D₃ and was observed within a physiologically relevant range. Importantly, addition of DBP suppressed the impact of 25(OH)D₃ on T cell responses depending upon its variant and concentration. Together, these data suggest that 25(OH)D₃ can be locally converted to 1,25(OH)₂D₃ by DCs and that the 1,25(OH)₂D₃ generated becomes available to T cells. This indicates that the outcomes of T cell responses to Ag are influenced by the bioavailability of 25(OH)D₃ to DCs, which in turn is affected by DBP concentration and genetic variant.

Materials and Methods

Cell isolation and cell culture

PBMCs were isolated by Ficoll gradient centrifugation from fresh leukocyte reduction system cones (provided by The National Blood Service, Birmingham, U.K.) or from healthy donors following informed consent in line with institutional and ethical committee approval. Similarly, samples from RA patients were obtained following informed consent in line with institutional and ethical committee approval. Isolated cells were washed twice with PBS and twice with MACs buffer (0.5% BSA and 2 mM EDTA in PBS) before resuspension at 1 × 10⁶ cells/ml for magnetic separation. For CD₄⁺CD₂₅⁺ isolation, CD₄⁺ T cells were first enriched using a negative selection Ab mixture (StemCell Technologies). CD₂₅⁺CD₄⁺ T cells were subsequently removed by incubation with anti-CD₂₅ microbeads (Miltenyi Biotec) and magnetic column separation. CD₄⁺CD₂₅⁻ T cells were resuspended in CellGro SCGM serum-free medium (CellGenix) supplemented with 50 U/ml penicillin and streptomycin. Monocytes were also isolated by negative selection using an Ab selection mixture (StemCell Technologies). For culture to DCs, monocytes were resuspended at 2 × 10⁶/ml in RPMI 1640 (Life Technologies/Invitrogen) supplemented with 10% FBS, 50 U/ml penicillin and streptomycin, and 200 µM glutamine (Life Technologies/Invitrogen) and then performed on Applied Biosystems 7500 or 7900 machines using assays on demand from Applied Biosystems (18S rRNA, 4319413E; CYP2B1, Hs01068017_m1). Amplification of cDNAs involved incubation at 50°C for 2 min and 95°C for 10 min followed by 40 cycles of 95°C for 15 s and 60°C for 1 min. CYP2B1 mRNA expression was then calculated relative to 18S rRNA. For RT-PCR, Go Taq Polymerase (Promega) was used with the following primer sets: Megalin forward, 5'-GGCCATCGATGTTGCTGTCTT-3' and reverse, 5'-GTGTTGGGTCCTCCTGCAT-3'; Cubulin forward, 5'-GGGCGTTCACTGCTTCTCA-3' and reverse, 5'-GAGTGATGTT-GTGGCCTTGT-3'; β-actin forward, 5'-CATCACGTTGACATGACG-3' and reverse, 5'-GATGACCCAGGATAGTGTG-3'. cDNAs were amplified using the following conditions: reverse transcription at 95°C for 3 min followed by 35 cycles of 95°C for 1 min, 53°C for 45 s, 72°C for 45 s, and a final extension at 72°C for 5 min.

COPD plasma samples

Plasma samples were taken from the West Midlands COPD collection, which had been set up to study COPD phenotypes and progression in relation to data from biological samples. Ethical approval had been granted by the local ethics committee, and all patients had given informed consent. DNA was extracted, quantified, and genotyped for single nucleotide polymorphisms (rs7041 and rs4588) in the DBP gene that encodes variants GC2, GC1F, and GC1S using methods described previously (34).

DBP, 1,25(OH)₂D₃, and 25(OH)D₃ measurements

DBP concentrations were measured by ELISA using a commercially available kit (Immunodagnostik, Bensheim, Germany). Total 1,25(OH)₂D₃ was measured by enzyme immunoassay (University of East Anglia) and 25(OH)D₃ by liquid chromatography-mass spectrometry (University of East Anglia). When collecting DC and T cell culture supernatants for 25(OH)D₃ and 1,25(OH)₂D₃ analysis, DCs were resuspended at 112,500 cells/ml and T cells at 450,000 cells/ml. DCs were matured with LPS (1 µg/ml) and T cells stimulated with anti-CD3/CD28—beads at a ratio of one bead to four T cells. Cultures were treated with 25(OH)D₃ at the indicated concentration with or without DBP (20 µg/ml) and incubated for 24 h. Because vitamin D species were found to degrade to approximately one third of initial levels before measurement in the absence of DBP (Supplemental Fig. 1), spontaneous degradation was accounted for by multiplying values of 1,25(OH)₂D₃ and 25(OH)D₃ 3-fold. DBP was added at the end of the experiment to all cultures as a protectant, and all samples were stored at −80°C before analysis.
Statistical analysis

GraphPad Prism3 software (GraphPad) was used for statistical analysis. The $p$ values were calculated using nonparametric Wilcoxon or Mann–Whitney tests as appropriate. The $p$ value ranges are indicated in figures as follows: *$p < 0.05$, **$p < 0.01$, ***$p < 0.001$.

Results

Modulation of T cell responses by 25(OH)D$_3$ supplementation requires the presence of APCs

We previously demonstrated that active 1,25(OH)$_2$D$_3$ could directly modify the outcome of T cell stimulation (20). However, because systemic levels of 1,25(OH)$_2$D$_3$ in vivo are potentially too low to influence T cell responses, we sought to determine whether sufficient 1,25(OH)$_2$D$_3$ could be locally generated from inactive 25(OH)D$_3$ during immune activation. To test this concept, we stimulated CD4$^+$CD25$^-$T cells with mature DCs (mDCs) in the presence of inactive 25(OH)D$_3$ and measured the effect on responding T cells. As shown in Fig. 1A, top panel, and Supplemental Table I, expression of the regulatory protein CTLA-4 and the frequency and absolute number of FOXP3$^+$CTLA-4$^+$ cells was strongly enhanced by addition of 25(OH)D$_3$. By contrast, both the frequency and absolute number of cells producing inflammatory cytokines was markedly suppressed by 25(OH)D$_3$ (Fig. 1B, 1C, Supplemental Table I). Importantly, the magnitude of response was similar to 1,25(OH)$_2$D$_3$ supplementation, suggesting that efficient conversion of 25(OH)D$_3$ had occurred. By contrast, when T cells were stimulated in the absence of APCs (by using anti-CD3/CD28–coated beads) we observed only a modest induction of CTLA-4 and little or no suppression of IFN-$\gamma$, IL-17, and IL-21 by 25(OH)D$_3$ (Fig. 1A–C, bottom panels, Supplemental Table II). The addition of active 1,25(OH)$_2$D$_3$ to bead-stimulated T cells was however still effective in modifying CTLA-4 and cytokine expression, indicating that bead stimulated cells were responsive to 1,25(OH)$_2$D$_3$ in the absence of APCs (Fig. 1A–C, lower panels, Supplemental Table II). These findings were reproduced using a number of different blood donors (Fig. 1D, 1E) and indicated that the presence of DCs was required for T cell responses to be effectively modified by 25(OH)D$_3$.

To test whether the apparent responses to 1,25(OH)$_2$D$_3$ in our DC-driven assays might involve CYP27B1 activity, we treated these stimulations with the CYP27B1 inhibitor ketoconazole. This
revealed that T cell induction of CTLA-4 upon 25(OH)D₃ supplementation was suppressed by ketoconazole, supporting a role for CYP27B1 activity (Fig. 2A). Moreover, although CYP27B1 mRNA expression is reported in both DCs and T cells (24, 35–37), their relative expression has not been formally compared. Thus, to examine whether the lack of T cell response to 25(OH)D₃ in the absence of DCs could relate to levels of the converting enzyme, we compared CYP27B1 mRNA expression in T cells and DCs before and after stimulation. This revealed that CYP27B1 mRNA was low in unstimulated T cells and immature DCs (iDCs) and that DC maturation with LPS strongly upregulated CYP27B1 mRNA (Fig. 2B). By contrast, CYP27B1 mRNA in T cells upon stimulation was significantly lower, supporting the hypothesis that relative to DCs, T cells may be poor convertors of 25(OH)D₃.

We next examined the 25(OH)D₃ conversion by mDCs and anti-CD3/CD28–stimulated T cells by measuring the concentrations of 1,25(OH)₂D₃ and 25(OH)D₃ in the supernatants of cultures supplemented with 25(OH)D₃ for 24 h. As shown in Fig. 2C, 1,25(OH)₂D₃ could be detected in 25(OH)D₃-supplemented DC cultures but was below the detection limit in T cell cultures even at 100 nM of 25(OH)D₃. Correspondingly, we found that ~30% of available 25(OH)D₃ substrate was used by mDCs, whereas only 4% was used by bead-stimulated T cells (Fig. 2D). These measurements give a useful estimate of the relative difference in conversion efficiency by DCs and T cells. Moreover, supernatants from 25(OH)D₃-supplemented DC cultures could induce CTLA-4 expression when transferred to bead-stimulated T cells, indicating they contained functionally significant levels of 1,25(OH)₂D₃ (Fig. 2E). Interestingly, parallel titration studies for 25(OH)D₃ and 1,25(OH)₂D₃ (Fig. 2F) revealed similar responses at equivalent concentrations of 25(OH)D₃ or 1,25(OH)₂D₃, thereby reinforcing the idea of effective local conversion by the DC.

Activated T cells can induce CYP27B1 expression and 1,25(OH)₂D₃ generation in DCs

Induction of CYP27B1 in response to LPS might be an important mechanism during an innate immune response to microbes; however, we were also interested in whether 1,25(OH)₂D₃ gen-

FIGURE 2. CYP27B1 mRNA expression correlates with 25(OH)D₃ conversion activity. (A) CD₄⁺CD₂5⁻ T cells were stimulated for 4 d with mDCs in the presence or absence of ketoconazole and total CTLA-4 expression in CD25⁺ T cells measured by flow cytometry. (B) CYP27B1 mRNA expression was measured in iDCs, LPS-mDCs, and unstimulated and bead-stimulated T cells by quantitative real-time PCR. Levels were normalized to 18S rRNA and are plotted relative to the unstimulated T cell control. Horizontal lines indicate median expression, and significance was tested by two-tailed Mann–Whitney tests. LPS-treated DCs (mDCs) and bead-stimulated CD4⁺CD25⁻ T cells were cultured for 24 h in the presence of 25(OH)D₃ at indicated concentrations and the concentration of 1,25(OH)₂D₃ measured at the end of the assay (C). Dotted lines indicate the sensitivity range of the assay. The percentage of 25(OH)D₃ used (D) was calculated by normalizing to the level in the medium alone control. Data are from a single experiment representative of two performed. (E) Supernatants from 25(OH)D₃-treated mDCs or bead-stimulated T cells were used to supplement bead-driven T cell stimulations. CTLA-4 expression was compared with the level in the presence of control medium. (F) CD₄⁺CD₂5⁻ T cells were stimulated with mDCs plus anti-CD3 in the presence of 25(OH)D₃ or 1,25(OH)₂D₃ at the concentrations shown. Following stimulation, cells were stained for CD3, CTLA-4, IL-17, IFN-γ, or IL-21 and analyzed by flow cytometry. Mean values from five experiments are plotted. Bars indicate SEM. *p < 0.05.
eration could occur in the absence of this DC maturation signal. To investigate this, we stimulated T cells using iDCs, which expressed low levels of CYP27B1 mRNA. We observed that, in isolation, iDCs were not able to generate sufficient 1,25(OH)2D3 to influence CTLA-4 expression (Fig. 3A). Surprisingly, however, following T cell activation by iDC, changes in CTLA-4, IL-17, IFN-γ, and IL-21 were found to be equivalent for both 25(OH)D3 and 1,25(OH)2D3-supplemented stimulations (Fig. 3B). This suggested that efficient 25(OH)D3 conversion still occurred and that during the stimulation process, CYP27B1 was induced. In support of this, we detected high CYP27B1 mRNA expression in cocultures of T cells and DCs (Fig. 3C). Importantly, CYP27B1 mRNA was induced only in the presence of both anti-CD3 and T cells, suggesting the need to activate T cells to stimulate CYP27B1 expression. To confirm which cells expressed CYP27B1, we sorted T cells and DCs after 20 h of stimulation and measured CYP27B1 mRNA expression in the two fractions. As shown in Fig. 3C, CYP27B1 mRNA was highly enriched in the DC fraction, indicating that activated T cells could induce CYP27B1 in DCs and again emphasizing the relative lack of CYP27B1 expression in T cells. For comparison, we also tested the ability of APCs other than cultured DCs to generate functionally useful amounts of 1,25(OH)2D3. This showed efficient 25(OH)D3 conversion when stimulating CD4+CD25−T cells with purified CD14+ monocytes (Supplemental Fig. 2A) or when culturing unmanipulated PBMC cultures that contained both CD14+ and CD14−CD11c+ cells with anti-CD3. Furthermore, mononuclear cells isolated from the blood and synovial fluid of patients with RA were also able to convert 25(OH)D3 (Supplemental Fig. 2B).

To distinguish whether cell contact or soluble factors were required for upregulation of CYP27B1 in iDC-driven stimulations, we used a transwell approach. As shown in Fig. 4A, CYP27B1 was not induced in iDCs that were separated from anti-CD3–treated T cells (transwell A). In contrast, soluble factors from wells containing DCs and activated T cells permitted some induction of CYP27B1 in DCs. However, the greatest induction of CYP27B1 occurred in DCs that were in direct contact with activated T cells (transwell B). Together, these data suggest the importance of surface molecule engagement for CYP27B1 induction in DCs. Consistent with these data, we found that treating DCs with a range of proinflammatory cytokines (IFN-γ, IL-1β, TNF-α, and IL-15), reported to influence CYP27B1 expression in other cell types (38–44), gave a small increase in the expression of CYP27B1 mRNA (Fig. 4B). Similarly, an agonistic Ab to CD40 also promoted CYP27B1 mRNA expression by the DCs. Notably, however, anti-CD40 used in combination with inflammatory cytokines resulted in the highest induction (Fig. 4B). These treatments were also found to upregulate several markers associated with DC maturation (Fig. 4C). Thus, together, these data indicate that maturation of DCs during coculture with activated T cells permits efficient induction of CYP27B1 in the DC and can be driven by surface engagement with CD40 and the release of inflammatory cytokines.

**DBP affects T cell responses to DCs**

Given that most circulating 25(OH)D3 is bound to DBP, which facilitates its uptake by cells, we determined the impact of DBP on T cell responses. Surprisingly, as shown in Fig. 5A, addition of purified DBP suppressed T cell responses to 25(OH)D3 in a concentration-dependent manner. Interestingly, responses to 1,25(OH)2D3 were much less affected (Fig. 5B), suggesting that DBP might preferentially restrict 25(OH)D3 uptake by DCs but have less impact on T cell response to 1,25(OH)2D3. Consistent with the effect of DBP on T cell phenotype in response to 25(OH)D3, we were also unable to detect generation of 1,25(OH)2D3 in the presence of DBP (Fig. 6A). Furthermore 25(OH)D3 did not decrease from input levels in these cultures, suggesting lack of availability to DCs (Fig. 6B). We considered that this inhibition of conversion might be due to absence of the DBP transporter proteins megalin or cubulin in DCs. Accordingly, we could not detect mRNA for megalin or cubulin in DCs in contrast to robust expression in proximal tubule epithelial cell lines (Fig. 6C). Overall, these data suggest a role for DBP in controlling the availability of 25(OH)D3 for immune regulation.

The three most common DBP variants, GC1S, GC1F, and GC2, have different abilities to bind 25(OH)D3 and 1,25(OH)2D3, their
$K_d$ values for 25(OH)D$_3$ being 0.9, 1.7, and 2.8 nM, respectively, whereas those for 1,25(OH)$_2$D$_3$ are 56, 160, and 240 nM, respectively (29). We therefore considered the extent to which the immune effects of vitamin D might be dependent upon DBP variants. We carried out mDC-driven T cell stimulations in the presence of plasma from individuals with at least one GC2 (low-affinity) or one GC1F (high-affinity) allele, but not both, and compared responses to 25(OH)D$_3$ supplementation. Plasma samples were taken from a COPD cohort, for which data relating to DBP genotype, DBP concentration, and vitamin D status were already available. The percentage increase in CTLA-4 expression at either 1 or 10 nM 25(OH)D$_3$ relative to baseline suggested a weaker response by the high-affinity GC1F group (Fig. 7A). This observation was consistent with the stronger 25(OH)D$_3$-binding GC1F variant, reducing 25(OH)D$_3$ availability to the DC compared with the weaker binding GC2 species. Using our GC2 patients who showed the widest spread of plasma DBP concentration (18–30 mg/dl), we also investigated whether variation in plasma DBP concentration could influence T cell responses to vitamin D. As shown in Fig. 7B, DBP concentration inversely correlated with percentage increase in CTLA-4 expression. Similar trends for DBP variant were seen for a smaller cohort of healthy individuals (Fig. 7C), supporting the possibility that DBP might influence the availability of 25(OH)D$_3$ to APCs and subsequently 1,25(OH)$_2$D$_3$ to T cells.

**Discussion**

A number of studies now support a function for 1,25(OH)$_2$D$_3$ on immune cells such as monocytes, DCs and T cells. Although active 1,25(OH)$_2$D$_3$ can directly influence T cells that express the VDR following activation, it is unlikely that circulating levels of 1,25(OH)$_2$D$_3$ are sufficient to have such an impact. It is known that APCs such as macrophages, monocytes, and DCs can upregulate the enzymatic machinery necessary to activate 25(OH)D$_3$ (22, 24, 42, 45). Furthermore, they can respond to the 1,25(OH)$_2$D$_3$ they generate in an autocrine fashion, as indicated by upregulation of the VDR target gene cathelicidin and the vitamin D–inactivating enzyme CYP24A1 (45, 46), as well as reduced Ag presentation (24) or enhanced antimicrobial activity (42). Thus, APCs may also be able to generate and locally secrete sufficient 1,25(OH)$_2$D$_3$ to directly influence their cognate T cell partners in a paracrine manner. However, such functional interplay relating to vitamin D metabolism between T cells and DCs has not been extensively studied. We approached this question using a previously characterized model in which exogenously added 1,25(OH)$_2$D$_3$ was found to have an impact on T cell responses, resulting in the downregulation of proinflammatory cytokines and the upregulation of the regulatory proteins CTLA-4 and FOXP3 (20). Using these changes in T cell phenotype as a readout for the availability of 1,25(OH)$_2$D$_3$, we observed that T cell responses in the presence of 25(OH)D$_3$ were virtually identical to those in the presence of active 1,25(OH)$_2$D$_3$ as long as DCs were present. The effectiveness of DCs as a source of local 1,25(OH)$_2$D$_3$ correlated with their
robust expression of CYP27B1-converting enzyme upon maturation with LPS. In contrast, T cells alone only modestly expressed this enzyme. Other studies have reported CYP27B1 expression in T cells (35–37). However, although these indicate that T cells could metabolize 25(OH)D3, few functional readouts have so far been reported. In addition, the concentrations of 25(OH)D3 required for any effects appear to exceed those expected in vivo (36, 37). By contrast, we have shown that the level of CYP27B1 activity in T cells is in fact relatively low compared with DCs, and enzyme activity is insufficient to markedly influence their phenotype, as measured by expression of a range of cytokines and regulatory associated molecules across physiologically relevant concentrations of 25(OH)D3.

Given the importance of DCs as a source of the CYP27B1-converting enzyme, the control of its expression is of interest. In line with the findings of others (24, 43), we observed that bacterial LPS, which signals through TLR4, could induce strong CYP27B1 mRNA expression in DCs. Induction of CYP27B1 by APCs in response to Gram-positive TLR2/1 ligands has also been observed (42, 43, 47). Thus, upregulation of CYP27B1 in

---

**FIGURE 5.** DBP suppresses 25(OH)D3-driven anti-inflammatory T cell responses. (A) CD4+CD25+ T cells were stimulated with mDCs plus anti-CD3 in the presence of 25(OH)D3 across the range 0–100 nM. Stimulations were cross-titrated with purified human DBP at the concentrations shown. Following stimulation, CD3+ cells were analyzed for CTLA-4, IL-21, IL-17, and IFN-γ expression by flow cytometry. Data are from one experiment representative of two performed. (B) CTLA-4, IL-21, IL-17, and IFN-γ expression was measured by flow cytometry after CD4+CD25+ T cells were stimulated with DCs in the presence of 10 nM 25(OH)D3 or 10 nM 1,25(OH)2D3 and purified human DBP at the concentrations shown.
APCs appears a central mechanism in vitamin D–regulated innate immune responses. In addition to DC maturation induced by microbial products, we observed that during the course of T cell activation, DCs matured sufficiently to induce functionally significant CYP27B1 expression. Although soluble factors from these cultures or recombinant proinflammatory cytokines permitted detectable CYP27B1 mRNA induction, more effective upregulation was observed when DCs were in contact with T cells. Consistent with this observation, agonistic CD40 Abs were also effective in stimulating CYP27B1 expression. Combined treatment with CD40 Abs and inflammatory cytokines supported the strongest induction of CYP27B1, similar to the additive effects of cytokines and TLR signaling upon CYP27B1 expression, as shown in other studies (40, 42, 43). Overall, our study provides further evidence that cognate interactions occurring between DCs and T cells, including CD40 ligation, promote the induction of CYP27B1 and subsequent metabolism of 25(OH)D3 at a level that is sufficient to regulate the T cell response. This mechanism could therefore be of importance in the control of immune responses under noninfectious settings, such as might occur in autoimmune responses. The data presented in this study demonstrate CYP27B1 activity in a range of myeloid cell populations, supporting the view that the expression of CYP27B1 could be a general feature of myeloid cell maturation. Indeed, it would be of interest to ascertain how myeloid cells from different tissues or disease states vary in their levels of CYP27B1 expression and activity. Furthermore, given that retinal hydrogenase, the enzyme that activates vitamin A, has been associated with the CD103+ subclass of gut-resident DCs (48), variations in CYP27B1 expression with particular DC subclasses would also be of interest.

A major issue relating to the impact of vitamin D biology on immune cells concerns the concentration of its various metabolites available under physiological conditions. We have observed that titrating 25(OH)D3 across physiological levels revealed efficient conversion and T cell modulation even at concentrations as low as 1 nM, although the magnitude of the response increased toward 100 nM, suggesting a broad dynamic range. Thus, the outcome of a T cell response that takes place in the presence of CYP27B1 expressing APCs is likely to be proportionally sensitive to the available 25(OH)D3. Such data are important, given the number of studies linking 25(OH)D3 status with autoimmune conditions (8, 49–52), in which alteration of the inflammatory/regulatory T cell balance is likely to be involved in the pathogenesis. At present, total vitamin D is used as an indication of vitamin D status.

**FIGURE 6.** DBP inhibits availability of 25(OH)D3 to DCs. LPS-treated DCs (mDCs) were incubated for 24 h in the presence of 100 nM 25(OH)D3 with or without 20 μg/ml DBP and the endpoint concentration of 1,25(OH)2D3 measured (A). Dotted lines indicate the sensitivity range of the assay. The percentage of 25(OH)D3 used during the assay (B) was calculated by normalizing to the level in the medium alone control. (C) RT-PCR analysis of megalin, cubulin, and β-actin expression in proximal tubule kidney epithelial cells (PTEC), mDCs, and iDCs. Data are from a single experiment representative of three performed. - RT, Without reverse transcriptase.

**FIGURE 7.** DBP genotype influences the magnitude of T cell responses to 25(OH)D3 supplementation. CD4+CD25+ T cells were stimulated with mDCs for 4 d at increasing 25(OH)D3 concentrations and supplemented with: 2.5% plasma from patients with COPD with at least one GC2 or one GC1F allele but not both (A, B) or 2.5% plasma from healthy donors with at least one GC2 or one GC1F allele but not both (C). CTLA-4 expression was measured by flow cytometry and plotted as percentage increase in expression at the given 25(OH)D3 concentration relative to 0 nM 25(OH)D3. Horizontal lines show mean values. Significance between GC2 and GC1F groups was tested by two-tailed Mann–Whitney tests (A, C) and linear regression analysis used to test association between CTLA-4 induction and DBP concentration (B).
However, a number of factors could influence its availability to target cells. An important candidate is DBP because the majority of vitamin D is bound to this protein in serum. Interestingly, it has recently been suggested that DBP levels can modify the relationship between vitamin D status and bone mineral density (53). Accordingly, the relationship between vitamin D status and immunological function might also be influenced by DBP, depending on the ability of immune cells to express DBP transporters. We observed that addition of DBP strongly suppressed T cell responses to 25(OH)D$_3$, reducing the magnitude of CTLA-4 induction and inflammatory cytokine suppression. Thus, although DBP may bind to the surfaces of immune cells including monocytes (54), neutrophils (55), and lymphocytes (56, 57), it appears that DBP actually restricts availability to DCs and consequently limits T cell responses to 25(OH)D$_3$. This contrasts with the ability of DBP to promote uptake of 25(OH)D$_3$ by some cell types including kidney cells (26), mammary cells (27), and osteoblasts (28). Interestingly, we did not detect any significant inhibition by DBP on responses to 1,25(OH)$_2$D$_3$, perhaps suggesting that the major effect of DBP is in preventing uptake of 25(OH)D$_3$ by DCs and that 1,25(OH)$_2$D$_3$ may be less inhibited than 25(OH)D$_3$ due to its lower affinity for DBP. Notably, our findings are consistent with those of Chun et al. (46), who showed that DBP attenuated its lower affinity for DBP. Notably, our findings are consistent with the pact of 25(OH)D$_3$ on CTLA-4 expression compared with the stronger binding GC1F genotype more effectively limits the immunological function might also be influenced by DBP, depending on the ability of immune cells to express DBP transporters. An increasing body of evidence suggests that vitamin D can have profound effects on the immune system. The present data reveal that the outcome of T cell activation is strongly influenced by the availability of the inactive 25(OH)D$_3$ to DCs, because, upon maturation, these cells upregulate CYP27B1 and generate local 1,25(OH)$_2$D$_3$ at a sufficient level for T cells to respond. Our data further suggest that the availability of 25(OH)D$_3$ depends on both the serum level of inactive 25(OH)D$_3$ and the concentration and genotype of DBP. Accordingly, the level of free vitamin D available to the immune system might be lower than that indicated by standard measures of vitamin D status but could be clinically relevant in the control of inflammatory disease.
