Substrate Rigidity Regulates Human T Cell Activation and Proliferation

Roddy S. O’Connor,* Xueli Hao,* Keyue Shen,† Keenan Bashour,† Tatiana Akimova,* Wayne W. Hancock,* Lance C. Kam,† and Michael C. Milone*

Adoptive immunotherapy using cultured T cells holds promise for the treatment of cancer and infectious disease. Ligands immobilized on surfaces fabricated from hard materials such as polystyrene plastic are commonly employed for T cell culture. The mechanical properties of a culture surface can influence the adhesion, proliferation, and differentiation of stem cells and fibroblasts. We therefore explored the impact of culture substrate stiffness on the ex vivo activation and expansion of human T cells. We describe a simple system for the stimulation of the TCR/CD3 complex and the CD28 receptor using substrates with variable rigidity manufactured from poly(dimethylsiloxane), a biocompatible silicone elastomer. We show that softer (Young’s Modulus [E] < 100 kPa) substrates stimulate an average 4-fold greater IL-2 production and ex vivo proliferation of human CD4+ and CD8+ T cells compared with stiffer substrates (E > 2 MPa). Mixed peripheral blood T cells cultured on the stiffer substrates also demonstrate a trend (nonsignificant) toward a greater proportion of CD62L neg, effector-differentiated CD4+ and CD8+ T cells compared with stiffer substrates (E > 2 MPa). Mixed peripheral blood T cells cultured on the stiffer substrates also demonstrate a trend (nonsignificant) toward a greater proportion of CD62L neg, effector-differentiated CD4+ and CD8+ T cells. Naive CD4+ T cells expanded on softer substrates yield an average 3-fold greater proportion of IFN-γ-producing Th1-like cells. These results reveal that the rigidity of the substrate used to immobilize T cell stimulatory ligands is an important and previously unrecognized parameter influencing T cell activation, proliferation, and Th differentiation. Substrate rigidity should therefore be a consideration in the development of T cell culture systems as well as when interpreting results of T cell activation based upon solid-phase immobilization of TCR/CD3 and CD28 ligands. The Journal of Immunology, 2012, 189: 1330–1339.
that forms the foundation for many adoptive immunotherapy approaches currently being pursued in clinical trials. They also suggest that the mechanical properties of the substrate used for immobilizing T cell surface receptor ligands, especially TCR/CD3 and CD28 receptor ligands, should be considered when interpreting basic studies of signal transduction and T cell activation.

Materials and Methods

Fabrication of silicone-based culture surfaces

Poly(dimethylsiloxane) (PDMS) surfaces were fabricated by mixing dimethylsiloxane monomer (Dow Corning Sylgard 184) with its corresponding cross-linking agent, according to manufacturer instructions. The ratio of cross-linking agent to base polymer was varied from 1:5 to 1:50. PDMS elastomer slabs of 32 mm × 43 mm with a thickness of ∼10 mm were deformed using a flat, cylindrical head, which makes a no-slip contact with the PDMS surface. A calibrated mass was applied to this head, producing a deflection of the PDMS slab. Hertzian contact between the head and PDMS was assumed (20), which allows estimation of the material’s Young’s modulus from the head diameter (D), deflection (δ), weight (m), gravitational constant (g), and Poisson ratio (ν), assumed to be 0.5 for PDMS using the following equation:

\[ E = \frac{(1 - \nu^2)mg}{2Dh} \]

Coating of PDMS surfaces with Abs for T cell stimulation

Cured PDMS elastomer was incubated with a goat anti-mouse IgG (Cappel, MP Biomedicals) in PBS overnight at 4°C. Unless otherwise indicated, a concentration of 1 μg/ml was used. Following PBS rinsing, a 1-h incubation with a blocking buffer containing 5% BSA was performed. After washing, antigen mAbs to human CD3e (5 μg/ml, OKT3; Roche Pharmaceuticals) and human CD28 (5 μg/ml, clone 9.3; gift of C. June, University of Pennsylvania) were captured by incubation in PBS for 2 h, followed by washing before use.

Primary cell preparation and cell culture

Primary PBLs were obtained under approval by the University of Pennsylvania Institutional Review Board. Purified total T cells, CD4+ T cells, or CD8+ T cells were isolated using RosetteSep isolation kits ( Stem Cell Technologies). Naive CD4+ T cells were obtained by further depletion of CD45RO+ cells using human CD45RO-specific magnetic microbeads, LD selection columns, and a VarioMACS system (Miltenyi Biotec). Lymphocytes were cultured in either X-VIVO 15 or RPMI 1640 (Lonza) supplemented with 5% human serum (GemCell) or 10% FBS (HyClone), respectively, with 10 nM HEPES, L-glutamine, penicillin G, and streptomycin. The 4.5-μm beads with immobilized anti-human CD3 and anti-human CD28 (a gift of B. Levine, University of Pennsylvania) were used in some experiments at a ratio of 3 beads to 1 cell. T cells were maintained in culture at a concentration of 0.8–1.0 × 10^6 cells/ml by regular counting on a Multisizer III particle counter (Beckman-Coulter). In some experiments, cells were also counted by flow cytometry using CountBright beads (BD Biosciences) and mAbs to human CD4 and CD8.

Quantitative real-time RT-PCR analyses for IL-2 mRNA

Total RNA was isolated from cells using a RNeasy kit (Qiagen). cDNA was generated by reverse transcription using a High Capacity cDNA Reverse Transcription Kit (Applied Biosystems, Carlsbad, CA). cDNA was amplified with a predesigned primer-probe set for human IL-2 (Hs00174114_m1; Applied Biosystems). A β-actin–specific primer-probe set (Hs999999_03_m1; Applied Biosystems) was used as a normalization control. Quantitative real-time RT-PCR (qRT-PCR) assays were performed on a 7500 Fast Real-Time PCR system thermal cycler (Applied Biosystems) using the comparative C_τ model. In experiments in which the stability of IL-2 mRNA was evaluated, CD4+ lymphocytes were seeded at 0.5 × 10^6 cells/well. After 4 h, the cultures were treated with or without cyclosporine A (10 μM; Sigma-Aldrich) or actinomycin D (5 μg/ml; Sigma-Aldrich) to inhibit de novo IL-2 mRNA transcription. Cells were harvested, as indicated, and IL-2 mRNA was determined by qRT-PCR analyses, as described above.

Abs and flow cytometry

At the indicated time following activation, cells were stained with a panel of mAbs to CD3, CD4, CD8, CD45RA, CD45RO, CD62L, CCR7, CD27, and LIVE/DEAD Aqua dye (Invitrogen). Flow cytometry was performed using a LSRII (BD Biosciences, San Jose, CA), and data were analyzed using FlowJo software (Tree Star, Ashland, OR). In experiments in which proliferation was assessed using CFSE dilution, cells were stained with 5 μM CFSE for 5 min, washed twice, and resuspended in culture medium prior to initiation of the culture, as indicated. Flow cytometry was performed on cells on day 3, and data were analyzed using the proliferation module as implemented in FlowJo.

Statistical analysis

Student’s t test for paired data, Wilcoxon rank sum, or a one-way ANOVA were performed using GraphPad Prism version 4.0a (GraphPad Software). A p value <0.05 was considered statistically significant.

Results

PDMS as a substrate with controllable rigidity for T cell activation and culture

PDMS, a biocompatible organosilicon polymer commonly used as a lubricant, anticaking agent in foods, and antibloating agent, was selected as a substrate for Ab immobilization. Following cross-linking of the base polymer, PDMS forms an elastomeric material with a highly hydrophobic surface (21). Proteins, including Ab, passively adsorb to this hydrophobic surface. Alteration of the cross-linking agent-to-base-polymer stoichiometry in the commonly used Sylgard 184 preparation of PDMS provides a simple method for varying the elastic modulus of PDMS from a Young’s modulus of >2.3 MPa (stiff) to a range of 50–100 kPa (soft) (Fig. 1A). Prepared this way, this material has been used to study the effects of substrate rigidity on fibroblast focal adhesion formation (4). Adsorption of anti-CD3 (OKT3) and anti-CD28 (clone 9.3) Abs to the surface of PDMS provides a system for activation of T cells on substrates with varying elastic modulus, analogous to standard immobilization on more rigid polystyrene tissue culture plastic or glass. Quantitative measurement of enzymatically coupled primary capture Ab (Fig. 1B) as well as fluorescently labeled OKT3 and clone 9.3 (data not shown) demonstrates that the amount of Ab adsorbed on PDMS surfaces with varying elastic modulus is equivalent despite changes in the ratio of base polymer to cross-linking agent. Both OKT3 and clone 9.3 also demonstrated stable binding over the course of 48 h, with <20% loss of Ab at 37°C in complete culture medium independent of the cross-linker ratio (Fig. 1C). Clone 9.3 appeared to demonstrate a slightly more rapid loss from stiff surfaces compared with soft surfaces; however, the quantity of bound clone 9.3 was not significantly different between the PDMS surfaces at 48 h, after which T cells typically transfer to uncoated culture vessels for log-phase ex vivo expansion using planar-activating substrates.

Initial evaluation of T cell activation demonstrated that softer PDMS stimulatory substrate increased IL-2 secretion (Fig. 1D). Because the stiffer PDMS substrates contain more cross-linking agent, we considered the possibility that one of the components in the cross-linking agent may be toxic, leading to nonspecific inhibition of T cell activation and IL-2 secretion. To evaluate this possibility, we simultaneously stimulated T cells with Ab-coated magnetic microbeads in the presence of PDMS with variable rigidity. Unlike T cells stimulated with Abs immobilized on the PDMS substrate, microbead-stimulated IL-2 secretion was comparable across the different PDMS surfaces, arguing against a toxic effect of PDMS elastomer or its cross-linking agent (Fig. 1D).

Because Ab density is an important factor affecting T cell activation and proliferation, we evaluated the ability of primary human peripheral blood CD4+ T cells to undergo proliferation in response to varying density of OKT3 and clone 9.3 on PDMS surfaces. We observed both Ab density-dependent and stiffness-dependent effects on T cell proliferation. Using a CFSE dilution...
FIGURE 1. A T cell culture surface with controlled elastic modulus can be generated using variably cross-linked PDMS. (A) The elastic modulus of PDMS was measured, as described in Materials and Methods. Horizontal bars represent the mean of four independent batches of PDMS. (B) PDMS surfaces were coated with the indicated concentration of biotinylated goat anti-mouse IgG. Adsorbed Ab was detected by incubation with HRP conjugated to streptavidin and tetramethylbenzidine, followed by measurement of the OD at 450 nm. Data presented are representative of two independent experiments. Symbols indicated replicate wells performed within the experiment. (C) Fluorescently conjugated Abs against CD3 (OKT3) and CD28 (9.3) were simultaneously applied to PDMS surfaces precoated with goat anti-mouse IgG at 5 mg/ml, followed by washing and blocking. The fluorescent signal intensity at the surface for each Ab was measured by fluorescence microscopy and normalized to the signal intensity observed on the 1:10 PDMS surface. Surfaces were stored for 2 d in serum-containing culture medium at 37˚C, 5% CO2, and the surface fluorescence was measured at the indicated time points. Bars represent mean change in fluorescence intensity with the 95% confidence interval for three independent experiments with five replicates per experiment. (D) Supernatants were collected from primary human CD4+ T cells grown in X-VIVO 15 culture medium on PDMS surfaces coated with OKT3 and clone 9.3 for 24 h. IL-2 was measured by ELISA. Cells were stimulated with anti-CD3/anti-CD28–coated microbeads and cultured in wells containing uncoated PDMS as a control. Data were analyzed by a repeated-measures one-way ANOVA and a Neuman-Keuls multiple comparison test for posthoc analysis. Values are means ± SD from four independent experiments (*p < 0.05 for PDMS 1–5 versus 1–25; **p < 0.05 for PDMS 1–5 versus 1–50 and 1–10 versus 1–50). (E) CFSE-labeled T cells were stimulated on the indicated PDMS surface coated with anti-CD3 and anti-CD28 for 3 d. CFSE content was assessed by flow cytometry.
assay, greater proliferation was reproducibly observed at 72 h on softer surfaces. The difference in proliferation became more pronounced as the coating concentration of the goat anti-mouse capture Ab decreased <1 µg/ml, with the proliferation completely lost on harder surfaces coated with Abs at low concentration (0.1 µg/ml; Fig. 1E).

Polyclonal expansion of peripheral blood T cells is enhanced by culture on softer substrates

The demonstration that anti-CD3 and anti-CD28 immobilized on PDMS substrates with a lower elastic modulus stimulate greater IL-2 secretion and short-term proliferation suggested that manipulation of substrate rigidity could be a useful parameter in the ex vivo expansion of T cells. We therefore evaluated the ability of PDMS substrates to support more long-term proliferation of T cells. We observed a graded increase in overall polyclonal expansion of naïve CD4+ T cells across PDMS substrates with decreasing Young’s elastic modulus (Fig. 2A). On average, a 4-fold increase in overall culture yield is observed when comparing the softest PDMS substrate (1:50 cross-linker to base ratio) with the stiffest PDMS substrate (1:5 cross-linker to base ratio). The difference in overall expansion is primarily due to a more prolonged log-phase growth rather than a difference in the rate of proliferation (Fig. 2B). This enhanced log-phase expansion correlates with a more prolonged blast phase, as shown by the increase in mean cellular volume during the course of the culture (Fig. 2C). Similar to IL-2 secretion (Fig. 1D), CD4+ T cells cultured on PDMS surfaces, but activated by anti-CD3 and anti-CD28 immobilized on microbeads rather than PDMS, demonstrate comparable proliferation supporting the nontoxic nature of PDMS and the dependency on PDMS immobilization for the observed enhancement in the T cell proliferative response (Fig. 2D). Experiments were also performed using soluble anti-CD3 and anti-CD28 Abs with goat anti-mouse IgG-coated PDMS surfaces to create an equilibrium-binding state that avoids the loss of Ab from precoated surfaces. We therefore evaluated the ability of PDMS substrates to support more long-term proliferation of T cells. We observed a graded increase in overall polyclonal expansion of naïve CD4+ T cells across PDMS substrates with decreasing Young’s elastic modulus (Fig. 2A). On average, a 4-fold increase in overall culture yield is observed when comparing the softest PDMS substrate (1:50 cross-linker to base ratio) with the stiffest PDMS substrate (1:5 cross-linker to base ratio). The difference in overall expansion is primarily due to a more prolonged log-phase growth rather than a difference in the rate of proliferation (Fig. 2B). This enhanced log-phase expansion correlates with a more prolonged blast phase, as shown by the increase in mean cellular volume during the course of the culture (Fig. 2C). Similar to IL-2 secretion (Fig. 1D), CD4+ T cells cultured on PDMS surfaces, but activated by anti-CD3 and anti-CD28 immobilized on microbeads rather than PDMS, demonstrate comparable proliferation supporting the nontoxic nature of PDMS and the dependency on PDMS immobilization for the observed enhancement in the T cell proliferative response (Fig. 2D). Experiments were also performed using soluble anti-CD3 and anti-CD28 Abs with goat anti-mouse IgG-coated PDMS surfaces to create an equilibrium-binding state that avoids the loss of Ab from precoated surfaces. A similar ∼4-fold enhanced CD4+ T cell expansion was observed, with the softer surfaces supporting an effect of PDMS rigidity rather than differential Ab binding between the PDMS surfaces (Supplemental Fig. 1).

Given the significant enhancement in polyclonal expansion of naïve CD4+ T cells, we evaluated the ex vivo expansion of a mixed population of CD4+ and CD8+ peripheral blood T cells, a population of cells that is more reflective of the starting population currently being employed for many adoptive immunotherapy studies. Consistently, the softer surface also supported an average 4-fold increase in overall T cell expansion compared with stiffer substrate (Fig. 3A, 3B). This effect was observed in both CD4+ and CD8+ T cells. Because the increase in expansion for a mixed population of cells could be explained by differential expansion of individual T cell subsets, we evaluated the surface phenotype of cells prior to expansion and at the end of the log phase of expansion. Table I shows that the ratio of CD4 to CD8 T cells was comparable between both conditions of rigidity following expansion. The surface expression of CD62L, a cell surface marker routinely used to distinguish memory from effector T cell subsets, also exhibited a trend (nonsignificant, \( p = 0.0745 \) for CD8+ T cells and \( p = 0.1821 \) for CD4+ T cells) toward more CD62L-negative cells following expansion on stiffer surfaces, as shown in Fig. 3C. We further evaluated the phenotypic and functional characteristics of T cells expanded on soft and stiff PDMS surfaces to examine regulatory T cells, effector function, and T cell exhaustion. Neither T cells derived from cultures on soft or stiff PDMS surfaces exhibit a regulatory phenotype based upon flow cytometric markers of regulatory T cells (Supplemental Fig. 2).

The impact of softer substrates on T cell activation and proliferation led us to consider whether substrate rigidity might also alter CD4+ T cell differentiation because the strength of the TCR signal has been reported to affect Th cell differentiation. The anti-CD3 and anti-CD28 conditions of activation used in our study have been reported to generate cells of a primarily Th1-like phenotype (24). We therefore evaluated the frequency of IFN-\( \gamma \)-producing T cells following expansion of naïve CD4+ T cells. Naïve CD4+ T cells isolated by magnetic bead separation were highly enriched for cells with a CD45RA+\( \times \)CD62L+ phenotype (Fig. 5A). Following expansion on either the soft or stiff surfaces, the cells exhibited comparable proportions of CD62L- and CCR7+ cells (data not shown); however, the cells expanded on soft surfaces exhibited a 3-fold increase in the proportion of cells capable of producing IFN-\( \gamma \) (Fig. 5B, 5C). Combined with the observed enhancement in expansion, softer surfaces produce a ∼1-log greater number of IFN-\( \gamma \)-producing T cells. Greater than 80% of T cells produce...
IFN-γ, independent of culture surface in the presence of exogenous IL-12, demonstrating that T cells expanded on stiff substrates are capable of differentiation (data not shown). Based upon these results, we conclude that substrate rigidity might be a useful parameter for controlling CD4+ T cell expansion, particularly in mixed T cell cultures in which the cytokine milieu may be difficult to control.

Discussion

This work is the first study to our knowledge demonstrating that the elastic modulus of a cell culture surface influences the activation, proliferation, and differentiation of T cells in ways that could be advantageous for adoptive immunotherapy. Previous studies established that T cells discriminate between surface-bound TCR/CD3 complex ligands and their corresponding soluble forms (8, 12). Our work extends this current body of knowledge, providing evidence that the mechanical properties of the underlying surface used for immobilization are also important, potentially modifying the forces that are generated by T cells and/or the forces sensed within the immune synapse affecting the T cell activation process.

PDMS was selected for our studies due to its established biocompatibility and stability, along with the ease by which its
mechanical properties can be modified through variation of the cross-linker–to-base-polymer ratio. It is possible that additional material properties of PDMS change with the variation in cross-linker ratio. Protein adsorption to a surface is highly dependent upon both the hydrophobicity and electrostatic properties of the surface (25). PDMS is well known to be highly hydrophobic, with a surface hydrophobicity, as measured by the contact angle of water, that changes little with variation in the cross-linker–to-base-polymer

![Graph C](image3.png)

**FIGURE 3.** The expansion of mixed human peripheral blood T cells is enhanced on soft substrates. (A) Representative growth curves for total T cells, CD4+, and CD8+ T cells expanded on 1:5 and 1:50 PDMS coated with OKT3 and clone 9.3 in X-VIVO 15 culture medium. CD4+ and CD8+ T cells were enumerated by flow cytometry, as described in Materials and Methods. (B) The overall number of population doublings achieved for total T cells, CD4+, and CD8+ T cells stimulated by 1:5 or 1:50 PDMS coated with OKT3 and clone 9.3. Results are derived from six separate experiments using T cells from independent healthy donors. The 1:5 and 1:50 conditions were compared using a paired, two-tailed Student t test (*p < 0.0008 for total T cells grown on a soft surface relative to hard; **p < 0.0013 for CD4+ T cells grown on a soft surface relative to hard; ***p < 0.0036 for CD8+ T cells grown on a soft surface relative to hard). (C) Representative data on the expression of the memory markers CD62L and CCR7 in T cell subsets prior to expansion and following expansion on PDMS substrates. The graphs to the right of the flow cytometry plots show a summary of the percentage of CD4+ or CD8+ T cells lacking CD62L expression at the end of the culture period. All cultures began with a mixed population of human peripheral blood CD4+ and CD8+ T cells from seven separate healthy donors.
We demonstrate comparable Ab adsorption and stability across the cross-linker–to-base ratios used in our study, which is largely consistent with other studies of PDMS surface hydrophobicity and passive adsorption of protein (27). Brown et al. (28), using a layer-by-layer polyanion coating on PDMS with variable stiffness, reported some differences in surface roughness and water contact angle following their surface treatment. These differences appeared to impact vascular smooth muscle cell spreading in the absence of serum; however, cell spreading was similar when serum was present.

Physical forces at the TCR/CD3 complex have been linked to intracellular signaling events. Dynamic imaging studies of T cells interacting with supported planar bilayers and solid glass supports demonstrate that TCR microclusters and signaling complexes initially form at the periphery of the immune synapse (19). This peripheral area of the immune synapse is rich in actin and myosin, with force exerted on many adhesive receptor-ligand interactions by actin-driven, lamellipodial extension of the T cell membrane as well as myosin-driven contraction of the actin network (9). The importance of actin-driven force in the generation of TCR signal transduction is highlighted by studies demonstrating that inhibition of actin polymerization affects T cell activation (12, 19, 29, 30). Inhibition of myosin L chain kinase by blebbistatin or the depletion of myosin IIA has also been demonstrated to severely inhibit TCR signaling, supporting a critical role for cell-generated force in the T cell activation process (10).

Changes in the stiffness of the TCR/CD3 ligand support substrate would be expected to dampen the forces applied to individual adhesive receptor-ligand interactions. The range of force necessary to induce signal transduction by the TCR compared with the force necessary to disrupt the mechanical linkage between the receptor and its ligand is currently unknown; however, bond strength and bond lifetime change with the application of a loading force (31). Whereas the bond between avidin and biotin ($K_d \sim 10^{-15}$) is one of the strongest noncovalent associations, with a lifetime ($1/k_{off}$) on the order of $\sim 10^9$ seconds, this bond's lifetime is reduced dramatically under load to $<1 \text{s}$ with a pN-range load (32). Much lower forces are therefore expected to have significant effects on the lifetime of bonds between Abs or TCRs and their ligands, which are several orders of magnitude weaker in their binding affinity. Whereas the softer surfaces used in our studies have sufficient stiffness to trigger TCR signaling, the net effect of the softer surface may be to provide prolongation of receptor-ligand binding and signaling, leading to more effective stimulation. Unfortunately, the testing of this hypothesis requires the ability to evaluate dynamic signaling in the context of measuring...
the lifespan of receptor-ligand interactions and/or molecular-scale forces, both of which are currently technically challenging in the context of living cells.

Although mechanical force appears to play a central role in the activation and maintenance of TCR signal transduction, it may also modify downstream signal transduction by the TCR and other receptors affecting immune synapse formation and stability. Focal adhesions in cells such as fibroblasts depend upon mechanical tension applied to adhesion sites for their assembly (4, 5, 33, 34). Many of the same proteins that regulate focal adhesion assembly, such as Pyk2, FAK, p130Cas, paxillin, vinculin, and talin, are also present within T cells at the immunological synapse (35–39). The presence of these proteins, and other mechanosensitive proteins within the immunological synapse, provides mechanism(s) by which forces at the synapse, modified by the substrate rigidity, could influence T cell signal transduction, synapse formation and stability, and the activation process.

It is possible that the observed effect of modifying the rigidity of T cell-activating substrates could also be relevant in vivo. Cytoskeletal changes within dendritic cells are reported to alter the process of T cell activation (40–43). MHC molecules and costimulatory ligands such as CD80 also appear to be anchored to the dendritic cell cytoskeleton (44, 45). Because the actin cytoskeleton represents a gel with viscoelastic properties not unlike PDMS, modification of the cytoskeleton may be a mechanism used by dendritic cells to alter synapse formation, dynamics, and ultimately the T cell activation process. Cells attached to solid substrates assume a cytoskeletal rigidity that is proportional to the rigidity of their attachment substrate (17). Although yet to be evaluated, the pliancy and tension of the surrounding extracellular...
matrix (ECM) within a lymph node most likely change quite dramatically during the course of an immune response as the lymph node undergoes marked hyperplasia and distention. Studies to evaluate the dynamic mechanical properties of the ECM within a lymph node or lymphoid tissue during an immune response are currently lacking, but should be an area of future study.

Our observation that substrate rigidity affects the Th cell differentiation of T cells could be explained by a number of factors. Although cytokines certainly play a critical role, differentiation of Th cells toward different fates also depends upon TCR ligand density and duration of signaling (46–49). Cell-ECM interactions have also been linked to the control of gene expression in cells. The PDZ-domain-containing transcription factors YAP and TAZ were recently demonstrated to be important nuclear mediators of ECM-stiffness–induced mesenchymal cell differentiation (50). These pathways or other mechanosensitive pathways might affect lymphocyte differentiation in ways that have not been previously considered, and may depend upon the mechanical properties of culture systems employed to study T cells.

In addition to the fundamental importance of our findings to the basic study of T cells, a culture system with altered mechanical properties may also have useful applications to the field of adoptive T cell immunotherapy. Anti-CD3 and anti-CD28 Abs immobilized either on planar plastic surfaces or plastic microbeads are a commonly employed system for activating T cells ex vivo (3, 24). Efficient expansion of T cells, especially from patients with cancer, represents a significant challenge. The observation of enhanced expansion on softer surfaces with retention of a mostly CD62Lhigh memory-like phenotype suggests that a softer substrate might increase the feasibility of adoptive immunotherapy for more patients, especially in challenging diseases currently lacking, but should be an area of future study.

Acknowledgments

We thank Dr. Carl June at the University of Pennsylvania and Dr. Michael Dustin at New York University for helpful discussions and critiques of the manuscript. We also thank Nicholas Vena, Christina Fang, and Trevor Cassidy for technical assistance with these studies. In addition, we thank Korey Demers, Carolina Martinez, and Michael Betts for assistance with flow cytometry.

Supp. Figure 1. Human T cell expansion is enhanced on soft substrates with excess soluble anti-CD3 and anti-CD28

CD4+ T cells were stimulated on PDMS surfaces coated initially with 1μg/ml goat anti-mouse IgG antibody. Surfaces were blocked as described in the material and methods section. In separate wells, CD4+ T cells were added in combination with soluble OKT3 and clone 9.3 (each at 1μg/ml) to PDMS surfaces previously coated with 1μg/ml goat anti mouse IgG. Following three days, the cells were transferred to uncoated culture flasks and expanded until termination of log phase growth. Parallel cultures using standard immobilized OKT3 and 9.3 were performed as a control. Cell number was enumerated by flow cytometry as described in the materials and methods. Data from three independent healthy donors is shown. The 1:5 and 1:50 PDMS conditions for standard coating and soluble OKT3 and clone 9.3 were compared using a paired, one-tailed Student’s t-test (P<0.0228 for CD4+ T cells stimulated on standard immobilized antibodies; P<0.0472 for CD4+ T cells stimulated with soluble antibodies).

Supp. Figure 2. Human Treg cell number and function is unchanged following expansion on soft/hard PDMS substrates

After three days the cells were transferred to uncoated culture flasks and expanded until termination of log phase growth. (A) The percentage of CD4+ Foxp3+ cells was enumerated by flow cytometry using human CD25 (BD Biosciences), CD4, CD127 and FOXP3 (clone PCH101) antibodies from eBioscience. Data presented...
is representative of three independent experiments with separate donors. (B) The methylation status of the Treg-specific demethylated region (TSDR) in the Foxp3 promoter was assessed following PCR amplification of the FOCP3 TSDR region and sequential restriction enzyme digest of the amplicon to calculate the percentage of methylated CpG islands in the TSDR region of FOXP3. A 0-5% methylation status in the TSDR promoter region was defined as unmethylated. Representative data from two independent donors is shown. (C) CD4+ CD25+ and CD4+CD25-T cells expanded from soft/hard surfaces were co-cultured with PBMC's from a separate donor at varying ratios (ranging from 1:1 to 1:4) in the presence of stimulatory CD3ε mAb-coated microbeads for 4-5 days. Proliferation was assessed by labeling the cells with CellTrace (Invitrogen) and analysis by flow cytometry.

Supp. Figure 3. Cytokine expression and exhaustion markers are similar on T cells expanded on soft and stiff PDMS substrates. Total T cells were stimulated on OKT3 and clone 9.3 coated PDMS and expanded until termination of log phase growth as described in the Materials and Methods. T cells were restimulated with PMA and ionomycin for 5 hrs in the presence of GolgiStop and Brefeldin A followed by surface staining for CD3, CD4, CD8. After paraformaldehyde fixation, the cells permeabilized and stained with monoclonal antibodies to CD27, PD-1, 2B4, Lag-3, IFN-g, TNF-a and Perforin. IFN-g and TNF-a expressing T cells were analyzed by flow cytometry in CD8+ and CD4+ T cell subsets as shown in panels A and B, respectively. The frequency of cells expressing Lag3, 2B4 and PD-1 were
enumerated by flow cytometry in CD8+ and CD4+ T cell subsets as shown in panels C and D, respectively.
