miR-29ab1 Deficiency Identifies a Negative Feedback Loop Controlling Th1 Bias That Is Dysregulated in Multiple Sclerosis

Kristen M. Smith,* Mireia Guerau-de-Arellano,† Stefan Costinean,‡ Jessica L. Williams,‡ Arianna Bottini,§ Gina Mavrikis Cox,* Abhay R. Satoskar,* Carlo M. Croce,‡ Michael K. Racke,† Amy E. Lovett-Racke,* and Caroline C. Whitacre*

Th cell programming and function is tightly regulated by complex biological networks to prevent excessive inflammatory responses and autoimmune disease. The importance of microRNAs (miRNAs) in this process is highlighted by the preferential Th1 polarization of Dicer-deficient T cells that lack miRNAs. Using genetic knockouts, we demonstrate that loss of endogenous miR-29, derived from the miR-29ab1 genomic cluster, results in unrestrained T-bet expression and IFN-γ production. miR-29b regulates T-bet and IFN-γ via a direct interaction with the 3′ untranslated regions, and IFN-γ itself enhances miR-29b expression, establishing a novel regulatory feedback loop. miR-29b is increased in memory CD4+ T cells from multiple sclerosis (MS) patients, which may reflect chronic Th1 inflammation. However, miR-29b levels decrease significantly upon T cell activation in MS patients, suggesting that this feedback loop is dysregulated in MS patients and may contribute to chronic inflammation. miR-29 thus serves as a novel regulator of Th1 differentiation, adding to the understanding of T cell intrinsic regulatory mechanisms that maintain a balance between protective immunity and autoimmunity. The Journal of Immunology, 2012, 189: 1567–1576.

N}

aive CD4+ T cells are activated in response to Ag stimulation as part of the adaptive immune response. Depending on the cytokine and environmental cues present at the time of activation, T cells differentiate along specific developmental pathways characterized by unique cytokine and transcriptional profiles (1, 2). IFN-γ–producing Th1 cells are important mediators of protective immunity against intracellular pathogens, but uncontrolled Th1 inflammation can lead to tissue damage and autoimmune diseases such as multiple sclerosis (MS).

MS is an inflammatory demyelinating disease of the CNS involving myelin-reactive IFN-γ– and IL-17–producing Th1 and Th17 cells (3–6). Many of the current MS therapies act by restoring the Th1/Th2 balance, and the effectiveness of therapeutics often correlates with reductions in Th1 markers such as T-bet

experimental autoimmune encephalomyelitis (EAE) and from patients with MS. Using mice deficient in miR-29, we have implicated miR-29 derived specifically from one of two genomic miR-29 clusters, miR-29a/b1, as critical in regulating the Th1 bias of activated T cells through repression of T-bet and IFN-γ. Further, IFN-γ contributes to miR-29 induction, demonstrating a novel regulatory pathway initiated through IFN-γ signaling. Elevated miR-29b in EAE mice and MS patients may therefore be reflective of chronic Th1 inflammation, adding to our understanding of T cell regulation and the relationship between regulatory molecules and autoimmune inflammation.

Materials and Methods

Mice

All procedures were performed in accordance with the guidelines of the Institutional Animal Care and Use Committee-approved protocols. Adult C57BL/6 mice (6–10 wk of age) were purchased from The Jackson Laboratory (Bar Harbor, ME), and myelin basic protein (MBP)-specific TCR transgenic (Tcr-tg) mice were obtained from Charles Janeway (Yale University, New Haven, CT). Homozygous floxed miR-29a/b1 mice (C57BL6 strain) were generated as follows: For the targeting construct, two homologous recombination arms were amplified by PCR on 129 Svl/J X C57BL/6 genomic DNA; a 3' arm of 471 bp and a 3' arm of 3857 bp. The genomic fragment to be deleted of 600 bp, containing the miR-29a and miR-29b1, was amplified the same way and cloned in between two loxP sites in a pFlox vector. The recombination arms together with the floxed genes were all cloned into Gateway vectors and then assembled together into a destination vector that represented the targeting vector. 129SvJ/X1 ES cells were electroporated with the targeting vector, and clones were screened by Southern blot. DNA was digested with SacI and labeled with a 3' probe. One positive clone was identified out of 336 screened. The mutant ES cell clone was injected into C57BL6/lacZ to create chimeras. Agouti pups were screened by PCR to verify the generation of heterozygous floxed miR-29a/b1 mice. Homozygous floxed miR-29a/b1 mice were bred to EIIaCre mice to induce ubiquitous deletion of the cluster. The portion of the targeting vector containing neoR is present in the knockout mice. miR-29a/b1 and miR-29b2c knockout mice were used at 6–10 wk of age.

Northern blot

Spleen and liver were dissociated between two frosted slides, and the lysate was washed in PBS, depleted of red cells by hypotonic lysis with ammonium chloride (NH4Cl), centrifuged, and resuspended in PBS. Total RNA was extracted with TRIzol (Life Technologies, Invitrogen), loaded and denatured on SDS-PAGE, and blotted on a Hybond N+ membrane (Amersham Pharmacia Biotech). The membrane was hybridized with a gamma-32P radioactive probe representing the antisense sequence of mature murino-miR-29a, incubated overnight, washed, and exposed to a PhosphorImager screen (Molecular Dynamics). The image was processed by using a Typhoon image processing system (Amersham Biosciences).

EAE immunization

Mice were immunized s.c. over four sites on the flank with 100 µl of an emulsion containing 200 µg myelin oligodendrocyte glycoprotein (MOG) 35–55 (CS Bio) in PBS and an equal volume of CFA (containing 200 µg heat-killed Mycobacterium tuberculosis, Jamaica strain). Mice also received 200 ng pertussis toxin (List Biological Laboratories) injected i.p. at the time of immunization and 48 h later. Mice were monitored daily for clinical signs of disease and were scored as follows: 0, no signs; 1, limp tail or mild ataxia; 2, complete ataxia; 3, paralysis of one hindlimb; 4, complete hindlimb paralysis; 5, moribund or death.

Human subjects and memory CD4+ T cell isolation

All human samples were acquired under Ohio State University Institutional Review Board-approved protocols in accordance with the guidelines of the Declaration of Helsinki. WBCs were obtained by leukapheresis from healthy donors (HD) or MS patients who were in clinical remission and had not undergone immunomodulatory treatments (treatment-naive). Memory CD4+CD45RO+ cells were isolated on an autoMACS Pro Separator with the Dead Cell Removal Kit (Miltenyi Biotec). Naive T cells were stimulated with irradiated wild-type splenocytes (1:4 T cells/feeder) and 10 µg/ml MBPACl-11 with the following cytokine/neutralizing Ab combinations: Th1 (no exogenous cytokines or neutralizing Abs), Th1 (0.5 µg/ml IL-12 and 5 µg/ml anti-IL-4), Th2 (10 ng/ml IL-4, 5 µg/ml anti–IFN-γ, and 3 µg/ml anti-IL-12), Th17 (25 ng/ml IL-6, 1 µg/ml TGF-β, 2 µg/ml anti–IFN-γ, 2 µg/ml anti-IL-4, and 0.65 µg/ml anti-IL-12), and inducible T regulatory cells (iTregs) (5 µg/ml TGF-β). Cells were analyzed at 72 h after activation.

For Supplemental Fig. 4, splenic CD4+ T cells were purified from MBP-specific Tcr-tg mice using MACS separation with the mouse CD4+CD25+ T Cell Isolation Kit II (Miltenyi Biotec) to obtain enriched naive T cells. Purified CD4+ T cells were activated using the same T cell/feeder ratio, Ag dose, and cytokine/neutralizing Ab combinations as above for the first 72 h. After 72 h, cells were removed from stimulation and expanded in IL-2. RNA was obtained at 24-h increments up to 120 h, and cells were re-stimulated on day 7 with PMA and ionomycin for 8 h.

FACS analysis

For ex vivo cytokine secretion profiles, splenocytes and lymph node cells were stimulated for 4 h with PMA and ionomycin in the presence of brefeldin A (activation mixture; BD Biosciences). For intracellular cytokine staining, cells were re-stimulated directly ex vivo (see Fig. 5) or on d 6 after culture (see Figs. 2, 3) for 4.5 h with BD Pharmingen activation mixture. All Abs were purchased from BD Biosciences or eBioscience. Cell surface markers were labeled with directly conjugated Abs diluted in PBS/10% FBS/sodium azide for 20 min at 4°C. Cells were fixed and permeabilized with BD Cytofix/Cytperm (BD Biosciences) for 30 min, then stained for intracellular cytokines and T-bet for 40 min in Perm/Wash buffer at 4°C. Data were acquired with a BD FACS Canto II flow cytometer (BD Biosciences) using FACS Diva software and analyzed using FlowJo 9.0 (Tree Star).

Luciferase assay

The 3’ untranslated region (3’UTR) segments containing the target sites for miR-29 from the human Tbx21 and Ifng gene were amplified from genomic DNA and inserted into the PGL3 control vector (Promega) using the XbaI site immediately downstream from the luciferase stop codon. Mutant constructs were generated by mutating 4 bp in the miR-29b seed region using the QuickChange XL Site-Directed Mutagenesis kit (Stratagene). HEK-293 cells were transfected with 800 ng firefly luciferase vector, 100 ng Renilla luciferase control vector, and 200 nM of precuror miR-29b or scrambled oligonucleotides (negative control precursor; Ambion) according to the manufacturer’s protocol. Cells were lysed in 1× Passive Lysis Buffer and assayed in triplicate using the Dual-Luciferase Reporter Assay System (Promega). Firefly luciferase activity was normalized to Renilla luciferase activity as measured by a Vertas microplate luminometer (Promega) and was then calculated relative to the scrambled control in each independent replicate.

Chromatin immunoprecipitation assay

T cells were stimulated with anti-CD3 and anti-CD28 for 48 h. The chromatin immunoprecipitation assay was performed as described previously (25). The cells were pulse sonicated for 5 ± 40% amplitude to shear the DNA into 200- to 1000-bp lengths. The primer set for the Stat1 site for PCR amplification of the miR-29a/b1 promoters was as follows: 5’-CCTGGTCGACATCTGAGAGGGG-3’ (forward) and 5’-CTCCCAAC-
CAAGGAGCTGA-3′ (reverse). PCR conditions were 94°C for 30 s, 60°C for 30 s, and 72°C for 30 s for 35 cycles. Integrated density values were calculated using Alphalmager image analysis software (α Innotech) and normalized to input DNA.

Statistical analysis

Parametric data were analyzed using an unpaired t test for single comparisons involving unpaired data sets (α = 0.05), paired t test for single comparisons involving paired data sets (α = 0.05), and two-way ANOVA with Tukey’s or Bonferroni’s post hoc test for multiple comparisons (α adjusted according to number of comparisons). Nonparametric data were analyzed using a Wilcoxon signed rank test. Statistical analysis of miR-29b expression in human memory T cells included a technical normalization based on positive controls, then a geometric mean normalization using the top 50 highly expressed miRNAs, followed by a Student t test for individual miRNA comparisons to calculate p values.

Results

miR-29b is associated with Th1 autoimmunity and directly interacts with the T-bet and IFN-γ 3′ UTRs

There are >1400 unique miRNAs identified in humans, and >700 in mice (miRBase v17). To narrow the field of candidate miRNAs related to Th1 autoimmunity, we used in silico target predictions to identify miRNAs predicted to target both T-bet and IFN-γ. T-bet mRNA contains an evolutionarily conserved miR-29 seed sequence at positions 245–251 of the 3′ UTR, and IFN-γ mRNA contains a similarly conserved seed match at positions 474–480 of the 3′ UTR. The predicted targets of miR-29b suggest that this miRNA may play an important role in Th1 inflammation, and thus the role of miR-29b in T cells was examined further.

T cells were purified from EAE and control immunized mice at 10 days postimmunization (dpi) and quantitative PCR (qPCR) analysis revealed that miR-29b was significantly increased in CD4+ T cells from EAE mice (Fig. 1A). This presented a scenario in which miR-29b is induced in a model of Th1 inflammation but, based on its predicted targets, would function to limit Th1 inflammation. Because of their regulatory nature, miRNAs may act as part of negative feedback loops. For example, miR-146a is induced downstream of TLR signaling and targets IL-1R-associated kinase 1 and TNFR-associated factor 6 (26). We therefore hypothesized that miR-29b may act in a similar negative feedback manner. As such, miR-29b would be induced in response to ongoing inflammation in EAE and would in turn regulate Th1 inflammation by directly targeting T-bet and IFN-γ.

To investigate this hypothesis, we sought to determine if T-bet and IFN-γ represent direct targets of miR-29b using luciferase assays. HEK-293 cells were cotransfected with miR-29b or a negative control miRNA and a firefly luciferase gene was linked to the target gene (IFN-γ or T-bet) 3′ UTR. miR-29b repressed luciferase activity of the construct containing the human T-bet 3′ UTR by 38 ± 2% relative to the negative control miRNA (Fig. 1B). This activity was copy number dependent, as shown by the additional repression of luciferase activity that was observed using a construct containing four T-bet untranslated region (UTR) inserts (Fig. 1B). When the conserved site in the T-bet 3′ UTR was mutated, luciferase expression was restored, demonstrating the direct interaction between miR-29b and the predicted site of hybridization. To validate a specific miRNA–target interaction between miR-29b and IFN-γ, we performed similar experiments assessing luciferase activity in cells cotransfected with miR-29b and luciferase linked to the human IFN-γ 3′ UTR. miR-29b significantly reduced luciferase activity by 23 ± 11% relative to a miRNA negative control, and mutation of the conserved miR-29 binding site abrogated this effect (Fig. 1C). These results indicate that miR-29b is able to interact with both the T-bet and IFN-γ 3′ UTRs.

FIGURE 1. miR-29b is increased during EAE and directly interacts with the 3′ UTRs of T-bet and IFN-γ. (A) CD4+ T cells were isolated from the spleens of mice with EAE or control mice receiving adjuvant alone (Ctrl) at 10 dpi, and miR-29b was quantified by real-time PCR. Fold changes are expressed relative to the average of control mice. Data are representative of four biological replicates per group, and values are means ± SEM. p = 0.01 (Student two-tailed t test). (B) HEK-293 cells were cotransfected with dual luciferase reporters and miR-29b or control miRNA. Values represent luciferase activity of constructs with one or four copies of the human T-bet 3′ UTR or a mutated miR-29 complementary site (T-bet 3′ UTR mut). (C) Luciferase activity of a construct containing the human IFN-γ 3′ UTR or a mutated miR-29 complementary region (IFN-γ 3′ UTR mut). Constructs were cotransfected as in (B). The ratio of firefly to renilla luciferase activity was normalized to the control miRNA within each experimental replicate. Data are means ± SD from three to six independent experiments, each performed in triplicate. **p < 0.01, ***p < 0.001 (Student two-tailed t test).

Generation of miR-29–deficient mice

miR-29 is encoded in two intergenic genomic clusters, the miR-29ab1 cluster and the miR-29bc2 cluster on human chromosomes 7 and 1, respectively. These two clusters encode three different miRNAs, miR-29a, miR-29b, and miR-29c, which share identical 5′ seed sequences and therefore have the capacity to regulate the same target genes. Indeed, we observed that miR-29a was also able to repress the T-bet luciferase construct (data not shown). This suggests that the homology among miR-29 family members may confer the ability to exert similar biological effects to varying degrees. We therefore aimed to dissect the relative contribution of each genomic cluster using a genetic knockout approach.

To determine the importance of endogenous miR-29 and the role of each genomic cluster, we genetically deleted the miR-29ab1 or the miR-29bc2 cluster (Supplemental Figs. 1, 3). Mice with floxed alleles of miR-29ab1 were bred with ElaCre mice to induce ubiquitous deletion, and deletion was confirmed by Northern blot and PCR (Supplemental Fig. 1B, 1C). Mature miR-29a and miR-29b were undetectable in activated T cells, providing additional confirmation of genetic deletion (Supplemental Fig. 1D). Although miR-29b is encoded in both miR-29 genomic clusters, deep se-
miRNA-29 CONTROLS Th1 FEEDBACK LOOP

Endogenous miR-29ab1 regulates T-bet and IFN-γ during T cell activation

To determine the role of endogenous miR-29 in regulating Th1 bias, purified CD4+ T cells from miR-29–deficient mice and wild-type littermates were activated with polyclonal anti-CD3/anti-CD28 stimulation. The percentage of T cells producing IFN-γ at 6 d was significantly increased from 5.3 ± 1% in wild-type T cells to 31.8 ± 3% in miR-29ab1–deficient T cells (Fig. 2A, 2B). There was a corresponding increase in IFN-γ MFI (Fig. 2C) and increased concentration of IFN-γ in the culture supernatants that accumulated over time (Fig. 2D). Similar effects were observed with T-bet expression. The percentage of T cells expressing T-bet was significantly increased from 27 ± 5% in wild-type T cells to 66 ± 8% in miR-29ab1–deficient T cells (Fig. 2E, 2F). There was also a significant increase in T-bet MFI (Fig. 2G), indicating that loss of miR-29ab1 results in higher T-bet expression on a per cell basis. Together, these data demonstrate that miR-29 derived from the miR-29ab1 cluster is necessary to control the frequency of cells that commit to the Th1 lineage and further regulates expression of T-bet and IFN-γ within the committed population. Using the miR-29b2c–deficient mice (Supplemental Fig. 4A), we analyzed the contribution of this miR-29 cluster to Th1 regulation. miR-29b2c had no effect on the percentage of IFN-γ+ cells (Fig. 3A) or T-bet+ cells (Fig. 3C) after 6 d of ThN activation. IFN-γ MFI (Fig. 3B) and T-bet MFI (Fig. 3D) were also unaffected. Together, these data indicate that the miR-29ab1 cluster is responsible for regulating IFN-γ and T-bet expression.

We next aimed to determine the effect of miR-29ab1 deficiency on the in vivo response to Ag challenge. Mice were immunized with
MOG peptide 35–55 in conjunction with CFA to induce EAE, and cells from the draining lymph nodes were analyzed at 7 dpi. CD4+ T cells from the draining lymph nodes of both wild-type and miR-29ab1–deficient mice expressed comparable percentages of the activation marker CD44 (Fig. 4A). We also observed comparable proliferation as measured by CFSE dilution during in vitro Th1 stimulation (Fig. 4B), indicating that miR-29ab1–deficient T cells are capable of becoming activated and proliferating to the same extent as wild-type T cells. However, the number of cells in the lymph nodes at 7 dpi is significantly decreased (Fig. 4C) compared with preimmunization, suggesting that activation-induced cell death is occurring. The decreased lymphoid organ cellularity in both naive and EAE mice suggests that there is either a defect in the generation or survival of mature lymphocytes, which may interfere with the ability to generate an adaptive immune response. To this end, we observed a trend ($p = 0.06$) toward increased CD4+ T cell death as assessed by annexin V/7-aminoactinomycin D (7-AAD) staining (Fig. 4D), suggesting that miR-29ab1–deficient T cells undergo apoptosis at an increased frequency during activation. Not surprisingly, this failure of T cell expansion and/or survival results in reduced EAE severity (Fig. 4E). Consistent with the reduced EAE clinical severity, miR-29ab1–deficient mice had reduced CNS cellular infiltration. Isolation of CNS cells demonstrated similar percentages of CD45lo CNS resident cells but a complete absence of CD45hi infiltrating cells in miR-29ab–deficient mice (Fig. 4F). This result was confirmed by H&E staining, which also showed an absence of cellular infiltration in the spinal cord of miR-29ab1–deficient mice at 17 dpi (Fig. 4G). These data demonstrate that systemic loss of miR-29ab1 results in protection from EAE due to an inability to generate a robust adaptive immune response and further suggest that loss of miR-29ab1 may promote phenotypic and functional deficits beyond its role in Th1 regulation that may impair the development of EAE, as was shown in a recent publication demonstrating early thymic involution in miR-29ab1–deficient mice (27).

**FIGURE 4.** Effects of miR-29ab1 deficiency on EAE. (A) Draining lymph nodes (inguinal and axillary) were obtained from MOG-immunized wild-type (ab1+/+) and miR-29ab1–deficient (ab1−/−) mice at 7 dpi, and CD4+ T cell activation was assessed by flow cytometry for the activation marker CD44. (B) Splenocytes from wild-type (ab1+/+) and miR-29ab1–deficient (ab1−/−) mice were Th1-polarized in vitro, and proliferation was assessed by CFSE dilution at 48 h postactivation. Data are means ± SEM from two biological replicates. (C) Cellularity of the lymph nodes preinduction and postinduction of EAE mice 7 dpi. Data are means ± SEM from two biological replicates. **$p < 0.01$ (Student two-tailed t test). (D) Splenocytes from wild-type and miR-29ab1–deficient mice were Th1-polarized as in (C), and apoptosis was analyzed by annexin V/7-AAD staining at 48 h postactivation. Data are means ± SEM from two biological replicates. (E) EAE disease course in MOG-immunized wild-type and miR-29ab1–deficient mice. Data are representative of six to eight biological replicates across two independent experiments. $p = 0.04$ (Mann–Whitney U test). (F) CNS cells were isolated by density gradient from the spinal cords of EAE mice at 17 dpi, and different cellular subsets were distinguished by surface expression of CD45. CD45lo represents the CNS resident population, and CD45hi indicates CNS-infiltrating cells. Cells were gated based on 7-AAD exclusion (live cells). (G) H&E stain of inflammation in the lumbar spinal cord of wild-type and miR-29ab1–deficient mice at 17 dpi (original magnification $×20$).
Given the role of miR-29 specifically within CD4+ T cells, we examined ex vivo T cells from naive mice to determine if miR-29ab1 deficiency promotes an inflammatory bias in the absence of immune challenge. T cells from both the lymph nodes (Fig. 5A) and spleen (Fig. 5B) of miR-29ab1–deficient mice produced significantly higher levels of IFN-γ relative to wild-type mice, and there was also a modest but consistent increase in IL-17 production. An increased percentage of CD4+ T cells expressing the activation marker CD44 was also observed in the spleen (Fig. 5C), suggesting that loss of miR-29ab1 promotes an activated, proinflammatory T cell phenotype in vivo. After establishing that miR-29 regulates inflammatory Th1 cell phenotypes in vitro and in vivo, we sought to identify what signaling pathway(s) engaged during Th polarization may regulate miR-29 expression.

miR-29b is induced as a result of T cell activation and through IFN-γ–mediated Stat1 signaling

The dynamics of miR-29a and miR-29b expression in various Th subsets (ThN, Th1, Th2, and Th17) were examined over the course of 5 d and after a short restimulation on day 7 (Supplemental Fig. 4). We observed maximal induction of miR-29a (Supplemental Fig. 4A) and miR-29b (Supplemental Fig. 4B) at 48–72 h, which corresponded with peak IFN-γ production in ThN and Th1 cells (Supplemental Fig. 4C). On the basis of this kinetic analysis, we chose the 72-h time point to analyze miR-29 induction further.

Purified naive CD4+CD62L+ T cells from MBP-specific TcR-tg mice were activated and differentiated under ThN, Th1, Th2, Th17, or iTreg-inducing conditions, and miR-29 levels were assessed 72 h postactivation. miR-29b was significantly increased in all Th subsets relative to preculture levels, and miR-29a was elevated in Th1 and Th17 conditions (Fig. 6A). We also assessed the impact of miR-29ab1 deficiency on Th subsets, including Th1, Th2, Th17, and iTreg (Supplemental Fig. 4D–G). Loss of miR-29ab1 resulted in a marked increase in the number of cells producing IFN-γ during Th1 polarization. miR-29ab1 deficiency had more modest effects on other Th lineages. This indicates that miR-29 may have a more global role in CD4+ T cell activation, in addition to its effects on IFN-γ production. Elevated miR-29b expression is maintained in Ag-experienced murine memory CD4+ T cells, as they express higher levels of miR-29b than naive CD4+ T cells ex vivo (Fig. 6B). miR-29b induction can also be extended to human T cell differentiation, as purified human naive CD4+ T cells were found to upregulate miR-29b after Th1 differentiation (Fig. 6C), indicating that miR-29 is induced during T cell activation and differentiation in both mouse and human.

Although miR-29b is expressed at comparable levels in all Th subsets, we explored the specific induction signals that occur during Th1 polarization, given the increased expression in EAE (Fig. 1A) and the positive association between IFN-γ and miR-29 expression during in vitro polarization (Supplemental Fig. 4). To identify potential Th1-associated transcriptional regulators of the miR-29ab1 cluster, we performed a promoter analysis on the conserved genomic sequence within 5 kb of the previously defined transcriptional start site (28). There were no predicted T-bet binding sites in the promoter region using a T-box consensus of CACNNNNGTG; however, there were three evolutionarily conserved IFN-γ–activated site (GAS) elements (Fig. 6D). To test directly the contribution of IFN-γ to miR-29b induction, T cells were activated under ThN conditions or ThN with IFN-γ neutralization. miR-29b was significantly reduced when IFN-γ was neutralized (Fig. 6E), suggesting that IFN-γ contributes to miR-29b induction. However, miR-29b expression was still elevated relative to prestimulation levels, suggesting that T cell activation or other stimuli may also synergize to promote miR-29b expression. Stimulation of T cells with exogenous IFN-γ significantly increased miR-29b expression above that of polyclonal T cell activation alone (Fig. 6F), demonstrating that IFN-γ is able to amplify the induction of miR-29b. Additionally, we verified direct STAT1 binding to the miR-29ab1 promoter region. DNA from activated T cells was immunoprecipitated with a STAT1-specific Ab and analyzed by PCR. A region of the IFN-γ promoter was amplified from input DNA and STAT1-immunoprecipitated DNA (Fig. 6G), serving as a positive control (25). Importantly, a conserved region of the miR-29ab1 promoter was also amplified from input DNA and STAT1-immunoprecipitated DNA (Fig. 6G). These data support a role for IFN-γ–induced STAT1 in the transcriptional regulation of the miR-29ab1 cluster, establishing a regulatory feedback loop (Fig. 6H). Furthermore, these findings identify a mechanism whereby miR-29b may become elevated in response to ongoing Th1 autoimmune inflammation, including EAE.

MS is associated with increased miR-29b in memory CD4+ T cells

To validate the relevance of miR-29b in human autoimmune inflammation, miR-29b expression was quantified in memory CD4+ CD45RO+ T cells from MS patients. We analyzed memory T cells because the memory T cell population of MS patients is enriched with autoreactive myelin-specific T cells (29). Memory T cells were purified to >95% purity using magnetic bead negative selection from 17 HD and 19 MS patients of various subtypes including relapsing-remitting MS (RRMS, n = 11), primary progressive MS (PPMS, n = 4), and secondary progressive MS (SPMS, n = 4). For quantification of miR-29b, we used the NanoString nCounter System, which is an extremely sensitive and specific method of mature miRNA quantification that counts individual
mature miRNAs and provides a digital readout of relative abundance (24). miR-29b was significantly increased by 2.25-fold in the MS population ($p = 1.1 \times 10^{-6}$), as well as in each MS subtype (Fig. 7A). We confirmed the presence of an active Th1 response in the MS population, finding significantly elevated expression of T-bet in MS and RRMS compared with HD (Fig. 7B). Although we analyzed IFN-$\gamma$ expression, we did not find any differences in expression in resting memory T cells of MS and HD (Fig. 7C). Together, these data indicate that miR-29b is elevated in CD4$^+$ T cells in both EAE and MS. The positive association between miR-29b and T-bet in MS patients' memory T cells suggests that miR-29b may be induced in response to ongoing Th1 inflammation, as observed in EAE (Fig. 1A) and consistent with a negative feedback model.

In a subset of patients, we analyzed expression of miR-29b after reactivation of resting memory cells. Notably, there was a significant decrease in miR-29b expression in MS patients, whereas expression of miR-29b in HD remained stable (Fig. 7D). These data suggest that the miR-29 regulatory axis may be dysregulated in MS, such that reactivation represses miR-29b, which would facilitate robust expression of the miR-29 targets T-bet and IFN-$\gamma$ and promote disease pathogenesis.

FIGURE 6. miR-29 is induced as a result of T cell activation and IFN-$\gamma$ signaling. (A) Purified CD4$^+$CD62L$^+$ T cells from MBP-specific TcR-tg mice were differentiated in vitro in unbiased (ThN), Th1, Th2, Th17, or iTreg conditions, and miR-29 expression was quantified at 72 h postdifferentiation. Fold induction of miR-29 postculture is quantified relative to preculture. Data are means ± SEM from three independent experiments. *$p < 0.05$, **$p < 0.001$ (ANOVA Bonferroni post hoc test). (B) Ex vivo qPCR analysis of miR-29b expression in naive CD4$^+$CD62L$^+$ and memory CD4$^+$CD62L$^-$ T cells from C57BL/6 mice. Data are normalized to average miR-29b expression in naive T cells. Lines depict mean expression within each group. ***$p < 0.001$ (Student two-tailed paired $t$ test). (C) miR-29b expression in human naive CD4$^+$CD45RA$^+$ T cells preculture and post-Th1 differentiation. Results are normalized to preculture expression within each experimental replicate. Data are means ± SEM from five independent experiments. *$p < 0.05$ (Wilcoxon signed rank test). (D) Graphical representation of sequence conservation between the miR-29ab1 locus on human chromosome 7 and mouse chromosome 6. The genomic sequence was used to identify potential IFN-$\gamma$–activated site (GAS) elements (consensus sequence TTC/ANNNG/TAA) within 5 kb of the miR-29ab1 transcriptional start site (TSS). Predicted GAS consensus sites are delineated by an asterisk. (E) Murine T cells were activated under ThN conditions with neutralization of IFN-$\gamma$. Fold induction of miR-29b is quantified relative to preculture, and a solid line connects paired samples. Data are from four independent experiments. *$p < 0.05$ (Student paired two-tailed $t$ test). (F) Murine T cells were stimulated with anti-CD3/anti-CD28 and exogenous IFN-$\gamma$, and miR-29b was quantified by qPCR. Percent increase was calculated relative to prestimulation miR-29b expression. Data are means ± SEM from three independent experiments. **$p < 0.01$ (Student paired two-tailed $t$ test). (G) T cells were activated in vitro with polyclonal TCR stimulation for 48 h, and chromatin immunoprecipitation assays were performed with an Ab specific for Stat1. DNA bound to Stat1 was purified and used as a template for PCR analysis. Primers specific for a confirmed Stat1 binding site in the IFN-$\gamma$ promoter were used a positive control (lanes 1–5). Stat1 was also bound to the miR-29ab1 promoter (lane 6). Lanes 1 and 4 represent 1% input DNA, and an isotype control Ab was used as a negative control in lanes 2 and 5. Numbers below each lane represent integrated density values relative to input DNA. Data are representative of two independent replicates. (H) Proposed miR-29 regulatory feedback loop, where IFN-$\gamma$–induced miR-29 represses T-bet and IFN-$\gamma$. The Journal of Immunology 1573
miRNA-29 CONTROLS Th1 FEEDBACK LOOP

FIGURE 7. Memory CD4+ T cells expressed increased levels of miR-29b in MS patients. (A) Memory CD4+CD45RO+ T cells were purified by negative selection (>95% purity) from HD and MS patients. miR-29b levels were quantified using the NanoString nCounter System, which provides a digital readout of individual mature miR-29b copies in each sample. Data are categorized as all HD (n = 17) and all MS (n = 19), as well as stratified according to MS subtype including relapsing-remitting MS (RRMS, n = 11), primary progressive MS (PPMS, n = 4), and secondary progressive MS (SPMS, n = 4). Lines represent mean expression. The p values were calculated by technical normalization based on positive controls, followed by a geometric mean normalization using the top 50 most highly expressed miRNAs and a Student t test for individual miRNA comparisons. (B and C) Quantification of T-bet (B) and IFN-γ (C) mRNA transcript in the purified memory T cells from (A). The p values were calculated using one-way ANOVA. (D) Resting memory T cells from a subset of HD (n = 5) and MS (n = 5) were reactivated with PMA and ionomycin. miR-29b levels were quantified using the NanoString nCounter System as in (A). AmiR-29b was calculated by subtracting the activated miR-29b count from the resting memory miR-29b counts. The p value was determined using a Student two-tailed t test.

Discussion

The transcription factor T-bet and cytokine IFN-γ act synergistically to coordinate type 1 inflammatory responses and are expressed by a variety of cell types, including APCs and lymphocytes. Their expression is necessary for protective immunity; however, the timing and duration of expression must be tightly controlled to prevent inflammatory and autoimmune diseases. We have identified a specific miRNA, miR-29b, that is associated with MS and EAE and regulates Th1 differentiation. Despite the strong sequence homology among miR-29 family members and the presence of duplicate copies of miR-29b in two genomic loci, genetic deletion of the miR-29ab1 cluster preferentially regulates the Th1 phenotype. In theory, all miR-29 family members should be able to negatively regulate expression of T-bet and IFN-γ based on their high degree of sequence homology. Consistent with deep sequencing data (22), we have found that the miR-29ab1 cluster is the primary source of miR-29 in activated T cells, and loss of the miR-29ab1 cluster therefore exerts a dominant effect on the Th1 phenotype.

Our genetic knockout data implicate a role for the miR-29ab1 cluster in Th1 regulation, including both mature miR-29a and miR-29b, and others have reported similar roles for both miRNAs (22, 23). Ma et al. (23) recently reported that miR-29a and miR-29b expression decreases during intracellular bacterial infection, whereas we have found that miR-29b is increased in MS patients' memory T cells. These findings suggest that miR-29 may function differently within specific cellular subsets and during the course of infection as opposed to autoimmunity. Importantly, the data also emphasize that the expression and function of individual miRNAs within a homologous miRNA family can be both cell type-dependent and context-dependent.

Despite the effect of miR-29ab1 deficiency on the Th1 phenotype in vitro and ex vivo, we observed that systemic loss of miR-29ab1 results in EAE resistance. There are several possibilities for this observation. First, peripheral lymphoid organs of miR-29ab1−/- deficient mice have significantly reduced cellularity. This global reduction in cell number suggests that miR-29 deficiency may affect the generation or survival of lymphocytes. In cancer, miR-29 acts as a tumor suppressor to repress expression of the anti-apoptotic molecules Mcl-1 (30, 31). However, we observed more apoptotic cell death during in vitro Th1 polarization. These results suggest that miR-29ab1 deficiency may render T cells susceptible to activation-induced cell death, either directly through targeting molecules involved in apoptosis or indirectly by inducing a state of hyperactivation and overproduction of IFN-γ. Lastly, miR-29 may have important functions in other cell types that impact the ability to develop EAE. Using a CD4 T cell-specific miR-29ab1 knockout may provide more conclusive information about the role of miR-29 in EAE specifically within this cellular subset. Nonetheless, our findings emphasize the important consideration that miRNAs are multifunctional, and miR-29 has other important roles in immune cells that remain to be elucidated.

miRNAs often act through repression of one central regulator or via repression of multiple target genes in the same pathway or gene network such as miR-181a targeting of multiple phosphatases downstream of TCR signaling (32). miR-29b appears to operate in a similar fashion by targeting several components of the Th1 pathway. Although Steiner et al. (22) and Ma et al. (23) have reported individual effects of miR-29 on T-box transcription factors and IFN-γ, respectively, we have found that miR-29 is able to regulate expression of both T-bet and IFN-γ. In fact, Steiner et al. (22) observed a more dramatic repression of IFN-γ with miR-29 than with small interfering RNA to T-bet, indicating that direct repression of T-bet alone cannot fully recapitulate miR-29b–mediated IFN-γ repression. In the same way that T-bet and IFN-γ can act in a feed-forward manner to promote their expression, miR-29–mediated Th1 regulation may be amplified through repression of both T-bet and IFN-γ. The individual contribution of T-bet versus IFN-γ repression may depend on a variety of complex factors, including miR-29 target site accessibility within the target transcripts. For example, the miR-29 complementary region of the IFN-γ 3′UTR lies in close proximity to the AU-rich elements (AREs), and the complex in vivo cross talk between these UTR elements may dictate overall IFN-γ mRNA stability. The relationship between miRNA binding sites and other UTR elements including AREs is undoubtedly complex. In some cases, miRNAs can antagonize ARE-mediated decay, whereas in other cases AU-rich motifs and miRNA machinery can cooperate to promote mRNA destabilization (33–35). Although miR-29b is capable of regulating both the T-bet and IFN-γ transcripts, the timing and cellular microenvironment may ultimately dictate the ability of miR-29 to repress their expression.

In this report, we have implicated Stat1 as a transcriptional regulator of the miR-29ab1 cluster. Stat1 stimulates transcription of IFN-γ–inducible genes through binding to the conserved consensus motif of GAS elements. The proinflammatory properties of IFN-γ are well established, but IFN-γ also has functions that limit inflammation such as induction of SOCS1 to attenuate cytokine signaling (10, 11, 36). The finding that IFN-γ promotes miR-29 expression identifies an additional regulatory function of IFN-γ. Although we have focused on transcriptional regulation of the miR-29ab1 cluster, which produces both mature miR-29a and miR-29b transcripts, the observation that mature miR-29b is preferentially...
upregulated in MS/EAE and in most Th subsets indicates that the miR-29ab1 cluster may undergo additional posttranscriptional regulation. Several posttranscriptional mechanisms can affect mature miRNA biogenesis or stability, including cross talk between the miRNA biogenesis pathway and intracellular signaling molecules, cis-acting modifications of mature miRNAs, and association of miRNAs with the RISC complex (37). Many factors can dictate the levels of mature miRNAs, and miR-29 expression may be determined by both transcriptional and posttranscriptional regulation.

We have validated a role for miR-29b in Th1 differentiation; however, we also observed upregulation of miR-29b in other Th subsets. In contrast to Ma et al. (23), we found that miR-29b was induced under all Th conditions examined. It is important to note, however, that we used an Ag-driven differentiation system, which could have differing effects on miR-29 expression. miR-29b may be induced in response to T cell activation alone, and lineage-specific cytokine and environmental cues may augment induction, similar to the coordinated regulation of T-bet expression by both TCR and cytokine signals (38, 39). In support of this conclusion, IFN-γ appears to play a role in miR-29b induction, but miR-29b is still induced, albeit to a lesser extent, with IFN-γ neutralization. Further investigation into the function of miR-29b in other T cell subsets and the specific induction stimuli that synergize to promote expression will be critical to understanding the complex role of miR-29b in immune regulation.

Based on the ability of IFN-γ to augment miR-29b expression, the increased expression observed in MS patients may occur as a consequence of the altered inflammatory environment in MS. Previous studies in MS have found differential expression of specific miRNAs in CNS lesions, whole blood, CD4+ T cells, or regulatory T cells (40–44). We have specifically focused on miRNA expression in memory CD4+CD45RO+ T cells. Autoreactive regulatory T cells (40–44). We have specifically focused on miRNA's role in autoimmunity.

In addition to their role in autoimmunity, some miRNAs are involved in the regulation of tumor suppressor genes and during T cell activation (51, 52). Additionally, miRNAs may negatively prevent miRNA-mediated regulation and occurs in cancer. Alternative polyadenylation leading to shorter 3′UTRs can also occur, as was recently demonstrated in Alzheimer’s disease (53). 3′UTRs can affect the regulatory potential of miRNAs such as miR-29b. miRNAs targeting 3′UTRs are affecting the regulatory potential of miRNAs such as miR-29b. This regulation is critical to understanding the complex role of miR-29b in immune regulation.
