http://www.jimmunol.org/content/190/4/1746
Advanced age is associated with alterations in innate and adaptive immune responses, which contribute to an increased risk of infection in elderly patients. Coupled with this immune dysfunction, elderly patients demonstrate impaired wound healing with elevated rates of wound dehiscence and chronic wounds. To evaluate how advanced age alters the immune response to cutaneous wound infection, we developed a murine model of cutaneous *Staphylococcus aureus* wound infection in young (3–4 mo) and aged (18–20 mo) BALB/c mice. Aged mice exhibited increased bacterial colonization and delayed wound closure over time compared with young mice. These differences were not attributed to alterations in wound neutrophil or macrophage TLR2 or FcγRIII expression, or age-related changes in phagocytic potential and bactericidal activity. To evaluate the role of chemotaxis in our model, we first examined in vivo chemotaxis in the absence of wound injury to KC, a neutrophil chemokine. In response to a s.c. injection of KC, aged mice recruited fewer neutrophils at increasing doses of KC compared with young mice. This paralleled our model of wound infection, where diminished neutrophil and macrophage recruitment was observed in aged mice relative to young mice despite equivalent levels of KC, MIP-2, and MCP-1 chemokine levels at the wound site. This reduced leukocyte accumulation was also associated with lower levels of ICAM-1 in wounds from aged mice at early time points. These age-mediated defects in early neutrophil recruitment may alter the dynamics of the inflammatory phase of wound healing, impacting macrophage recruitment, bacterial clearance, and wound closure. The *Journal of Immunology*, 2013, 190: 1746–1757.

A
n estimated $25 billion in United States health care expenditure is spent on care of chronic, nonhealing wounds (1). One patient subpopulation, the elderly, account for a major portion of patients afflicted by chronic and infected wounds (1–3). Aging is associated with a decline in immune function, which can elevate rates of wound infection and delay wound closure in these patients (4–6). Advanced age is associated with a general decline in innate and adaptive immune function that contributes to an increased susceptibility to opportunistic bacterial and viral infections in the elderly (2, 7–9). Underlying this elevated susceptibility to infection are deficits in host recognition, phagocytosis, migration, and activation of a pathogen-specific adaptive immune response (10–13). In addition to the immunosenescence that accompanies aging, advanced age is also marked by heightened levels of circulating proinflammatory mediators in the absence of an inciting stimulus, a state referred to as “inflamm-aging” (14, 15). Taken together, these phenomena are thought to contribute to poor outcomes following infection or trauma in clinical and animal models of aging (2, 16–20).

Alongside playing a critical role in eradication of foreign pathogens, the innate immune response is also crucial to tissue repair, another physiologic response compromised by aging. Cutaneous wound repair is a complex process, marked by immune cell infiltration and inflammation, fibroblast and keratinocyte proliferation, angiogenesis, and remodeling of the extracellular matrix to ensure restoration of the normal skin barrier (5, 21–24). Natural and succinct progression through these interdependent stages of wound healing is required to ensure rapid and adequate repair of epidermal and dermal architecture. Clinical observations reveal that elderly patients have an impaired response to cutaneous injury, resulting in elevated rates of wound dehiscence and subsequent chronic wounds (1, 25). Nonhealing wounds in this patient population have an increased risk of infectious complications. This risk is associated with higher morbidity and mortality, as well as infectious spread in long-term care facilities (26). Moreover, older patients are more susceptible to postsurgical infections and subsequent problematic wound closure with costly prolonged hospital stays (2, 25).

Laboratory studies using murine models of cutaneous injury have substantiated the aforementioned clinical findings as advanced age has been shown to alter the dynamics of all stages of the wound repair process (27–30). Evidence suggests age-associated differences in the magnitude and duration of neutrophil and macrophage infiltration into the wound bed during the inflammatory phase of wound healing (27, 29). These phagocytes are instrumental in limiting infectious spread and regulation of the
temporal progression through the early phases of wound closure (22, 31, 32). Despite compromised immune function and increased rates of infectious wound complications in the elderly, the impact of advanced age on the host immune response to cutaneous wound infection has been neglected. *Staphylococcus aureus* is a common dermatopathogen that accounts for at least 75% of skin and soft tissue infections and 30% of surgical-site infections, with a dramatic increase in *S. aureus*-associated surgical site infections to 50% in patients >65 y of age (2, 33, 34). We developed a cutaneous excisional *S. aureus* wound infection model in young (3–4 mo) and aged (18–20 mo) BALB/c mice. Using this model, we found that advanced age is associated with heightened bacterial colonization and delayed wound closure due to reduced innate immune cell recruitment.

**Materials and Methods**

**Animal model**

Three- to 4-mo-old (young) and 18- to 20-mo-old (aged) BALB/c mice (Charles River Laboratories, Inc. [Agawam, MA, and Stone Ridge, NY]) were used to determine age-dependent differences in response to cutaneous wound injury and infection. All animal studies were approved and performed with strict accordance to the regulations established by the Loyola University Chicago Animal Care and Use Committee. Following acclimation at Loyola’s Animal Care Facility, young and aged mice were subjected to dorsal excisional cutaneous injury as previously described (35). Briefly, mice were administered 100 mg/kg ketamine and 10 mg/kg xylazine i.p. followed by i.p. saline to ensure systemic distribution of the anesthetic. Once the mice no longer responded to firm pressure applied to their hind limb, their dorsa were shaved and cleansed with ethanol pads. Mice were then subjected to six dorsal full-thickness (skin and panniculus carnosus) cutaneous wounds with a 3-mm dental puncture biopsy (Acuderm, Ft. Lauderdale, FL). Immediately after injury, mice received ~10^6 CFU/10 μl *S. aureus* and were returned to their cages on heating pads. Following arousal from anesthesia after injury and infection, no overt difference in grooming, mobility, activity, and nutritional status were observed between young and aged animals. A low inoculum of bacteria was chosen to prevent sepsis, which is known to negatively impact wound healing (36). *S. aureus* Newman strain was grown overnight in tryptic soy broth (TSB) at 37˚C under constant agitation. The next day, 1 ml *S. aureus* in TSB was resuspended in 2 ml fresh TSB and incubated at 37˚C for 2 h to ensure mid-logarithmic growth at the time of application to cutaneous wounds. Bacterial concentration (CFU per milliliter) was determined by absorbance at 600 nm and the final inoculum was confirmed by back-plating on mannitol salt agar (MSA; BD Diagnostics, Sparks, MD). Mice were sacrificed at days 1, 3, 7, and 10 after injury and infection. The pelt was removed and photographed to measure wound size as described below. A larger 5-mm puncture biopsy was used to remove the 3-mm wounds. One to two wounds from each animal were used to examine for bacterial colonization and for ex vivo phagocytosis, as well as flow cytometric analysis of wound immune infiltrate and cytokine and chemokine analysis as detailed below. Blood was obtained via cardiac puncture for flow cytometry analysis, as well as the bacterial assay.

**Bacterial colonization**

Skin, spleen, and kidney were each homogenized in 1 ml sterile PBS, and 10-fold serial dilutions to 10^6 were plated on MSA plates (BD Diagnostics), Heparinized whole blood was directly plated onto MSA plates. Plates were incubated at 37˚C for 24–48 h and colonies were counted to determine levels of bacterial colonization. Significant bacterial dissemination to spleen, kidney, and blood was not observed (data not shown). For wound colonization data, one wound from each individual animal was used to represent an n of 1 and experiments were repeated three to four times at each time point.

**Wound size**

Wound size was evaluated by digital photography and image analysis as previously described (35). Briefly, at days 1, 3, 7, and 10 all six wounds per animal were photographed with a Canon EOS SLR digital camera. Each pelt was photographed at a fixed distance of 20 cm with a ruler placed within the frame of each photograph. Photoshop 7.0 (Adobe Systems, San Jose, CA) was used to determine the number of pixels in the open wound area using the magic wand tool, with zoom at 100% and a tolerance setting of 60. Separate animals were sacrificed immediately following wound injury, and wound size was determined to represent day 0. Wound areas at each time point were compared with day 0 wounds: (pixels at days 1–10/ pixels at day 0) × 100 were used to determine the percentage open wound area at each time point. The percentage open area of the six wounds from each animal were averaged to give one value for each animal, such that the average of six wounds is an n of 1 individual animal. Data represents three to four replicate experiments.

**Skin and whole blood flow cytometry**

Single-cell suspensions of wound cells for flow cytometry were generated as previously described (37). At days 1–7 after injury and infection, animals were euthanized, pelt removed, and wounds excised using a 5-mm punch biopsy. Two wounds were used to achieve an adequate total cell yield and represent an n of 1 individual animal. Diced wounds were incubated overnight at 4˚C in RPMI 1640 culture media containing 10% FBS (HyClone, Logan, UT), 2 mM 1-glutamine (Life Technologies, Grand Island, NY), 1% penicillin/streptomycin (Life Technologies), 2 mg gentamicin sulfate (Mediatech, Manassas, VA), and 0.3 mg dispase II (Roche Diagnostics, Indianapolis, IN). The next day, tissue pieces were removed and subjected to further enzymatic digestion with 1 mg collagenase from *Clostridium histolyticum* type 1A (Sigma-Aldrich, St. Louis, MO), 1.2 mg DNase I from bovine pancreas grade II (Roche Diagnostics), and 1 mg hyaluronidase from bovine testes type 1-S (Sigma-Aldrich) in RPMI 1640 with 10% FBS, 2 mM L-glutamine (Life Technologies), 1% penicillin/ streptomycin (Life Technologies), 2 mg gentamicin sulfate (Mediatech), and magnesium chloride hexahydrate for 2 h at 37˚C. After 2 h, these solutions were combined and debris was removed by filtration with a 70-μm filter. Cells that remained adherent to the tissue culture plastic were treated with Accutase (eBioscience, San Diego, CA) for 5–8 min at 37˚C followed by vigorous pipetting. Cells were washed and adjusted to 1–5 x 10^6/ml. Cells were blocked for 20 min with Fc block (anti-CD16/CD32, eBioscience) and rat IgG (Jackson ImmunoResearch), and then stained with PE-Cy7-F4/80 (eBioscience), FITC-Gr-1 (eBioscience), allopoxycyanin-CD3 (eBioscience), or allopoxycyanin-TLR2 (eBioscience). Cells were washed twice and then resuspended in flow buffer (1% BSA, 0.1% sodium azide, and 2mM EDTA in PBS). For blood analysis, heparinized whole blood was collected and “manufacured” using the same protocol as above. Whole blood (100 μl) was blocked for 20 min with Fc Block and rat IgG and then stained with PE-Cy7-F4/80, FITC-Gr-1, and PE-CXCR2. Following staining, erythrocytes were lysed with 2 ml Easy-Lyte solution (Leinco Technologies) for 11.5 min. Lysis was terminated by addition of 2 ml ice-cold wash buffer (Leinco Technologies). Cells were washed twice in flow buffer and resuspended in 500 μl flow buffer. Both skin and blood samples were collected on the FACSCan-I and FACS LSRFortessa (BD Biosciences, San Jose, CA) and data were analyzed by FlowJo software (Tree Star, Ashland, OR). Fluorescence minus one control staining and single-color controls were used to determine positive staining.

**Phagocytosis and FcγRIII staining**

Following isolation, wound cells were subjected to pHrodo-*S. aureus* phagocytosis as previously described (37). Cells were resuspended to 1 x 10^7 cells/ml in phagocytosis buffer (PBS [Life Technologies]) with 20 mM HEPES [pH 7.4]) for the manufacturer’s instructions (Invitrogen, Carlsbad, CA). pHrodo-*S. aureus* BioParticles (Invitrogen) were reconstituted to 1 mg/ml in phagocytosis uptake buffer and then opsonized with rabbit polyclonal IgG Abs (Invitrogen) for 1 h at 37˚C. Control tubes for each animal were placed on ice (4˚C) and experimental tubes placed at 37˚C for 15 min to allow for temperature equilibration. pHrodo-*S. aureus* was resuspended at a batched 1.0 x 10^6 cells/cell rate and incubated for 0–60 min at 4˚C (control) or 37˚C (experimental), after which phagocytosis was stopped by addition of 2 ml ice-cold phagocytosis uptake buffer and placement on ice. Cells were blocked with rat IgG and anti-FcγRII (R&D Systems, Minneapolis, MN) to block FcγRI and FcγRII, respectively, for 20 min at 4˚C. Samples were then stained with PE-anti-FcγRII (R&D Systems) for 30 min followed PE-Cy7-anti-F4/80 and FITC-anti-Gr-1 for 30 min at 4˚C (38). Cells were washed twice, resuspended in flow buffer, and phagocytosis and FcγRII expression on wound neutrophils and macrophages were examined by flow cytometry. Data were acquired on the FACSCan-I (BD Biosciences) and analyzed by FlowJo software (Tree Star).

**Chemokine analysis**

One wound from each animal was homogenized in 1 ml cell lysis buffer (BioRad, Hercules, CA) supplemented with factor 1, factor 2, and PMSF per the manufacturer’s instructions. Homogenates were sonicated at 30%, syringe-filtered (25 μm), and chemokines (KC, MIP-2, and MCP-1) as well as adhesion molecules (ICAM-1) were analyzed by ELISA (R&D Systems) (39).
In Vivo Chemotaxis

Young and aged mice were administered 100 mg/kg ketamine and 10 mg/kg xylazine followed by saline to ensure systemic distribution of the anesthetic. Once the mice no longer responded to firm pressure applied to their hind limb, their dorsums were shaved and cleansed with ethanol pads. In the dorsal subcapular midline, mice were then injected s.c. with saline vehicle (50 μL) or 100 or 1000 pg recombinant mouse KC in a volume of 50 μL. Mice were sacrificed 8 h after injections. The injection site and surrounding tissue were excised with an 8-mm punch biopsy and subjected to digestion as outlined above (37). Neutrophil recruitment to the injection site was evaluated by flow cytometry as described above. Data are expressed as fold change of baseline neutrophil recruitment after saline injections.

**Statistical analysis**

Data are shown as mean ± SEM of each group. One wound, or an average of wounds as described above, from each animal was used to reach an n of 1, such that an n of 12 represents 12 individual animals. Data were analyzed by a Student t test or one-way or two-way ANOVA with a Tukey post hoc test, respectively, and, when appropriate, using GraphPad Prism 5 (GraphPad Software, La Jolla, CA). A p value ≤0.05 was considered significant.

**Results**

**Bacterial colonization and wound closure is impaired with advanced age**

To determine the impact of advanced age on the innate immune response following cutaneous injury and *S. aureus* infection, we developed a model of cutaneous wound infection in young and aged mice to evaluate bacterial colonization and wound size at days 1, 3, 7, and 10 after injury and infection. Bacterial colonization in wounds from aged mice were elevated over the time course examined as compared with young mice, with post hoc significance observed at day 3 (Fig. 1, p < 0.05). Levels of wound bacterial burden were unaltered in aged animals at day 7 as compared with day 3, whereas gradual reduction in wound bacterial content was observed in young animals by day 7. Moreover, by day 10, wounds from young mice averaged $10^3$ CFU/ml, compared with $10^6$ CFU/ml in aged animals. In parallel to these studies, wound size was evaluated by digital photography and image analysis (Fig. 2A). Compared to young mice, wounds from aged mice had a larger percentage of open wound area remaining at days 3 and 7 following injury and infection (Fig. 2B, p < 0.05), with incomplete closure at day 10. At day 3, wounds in aged animals remained ~80% open as compared with ~66% in young mice (Fig. 2B, p < 0.05). By day 7, an ~2-fold increase in percentage open wound area was observed in aged mice as compared with young mice (Fig. 2B, p < 0.05). The persistent open wound bed at day 10 in aged animals (~11 versus ~0.9% in young mice) could result in subsequent infectious complications in aged mice. Taken together, these findings recapitulate clinical observations of increased infectious complications and delayed healing with advanced age.

**Host recognition is not altered following injury and infection**

Previous studies have reported decreased TLR expression in various innate immune cell subsets with advanced age (reviewed in Refs. 6, 10). TLR1, TLR2, and TLR6 play critical roles in early host recognition of Gram-positive pathogens, and loss of TLR2 or downstream mediators of TLR signaling, such as MyD88, results in increased susceptibility to *S. aureus* infection (40–43). Given differences in bacterial colonization at day 3, we chose to evaluate TLR2 expression on resident tissue macrophages (F4/80+Gr-1− cells from uninjured skin) as well as on infiltrating wound leukocytes in aged mice relative to young mice (Fig. 3A). In aged mice, a reduction in the absolute number of TLR2+ resident tissue macrophages (Fig. 3B, p < 0.05) was observed compared with

![FIGURE 1](http://www.jimmunol.org/)

**FIGURE 1.** Wound bacterial colonization at days 1–10 following cutaneous injury and *S. aureus* infection. Young BALB/c mice (3–4 mo, filled circles and solid line) and aged BALB/c mice (18–20 mo, filled squares and dashed line) received six 3-mm dorsal cutaneous wounds followed by $10^5$ CFU *S. aureus* per wound. At days 1, 3, 7, and 10 after injury and infection, mice were sacrificed and bacterial colonization was determined by growth on MSA plates. Data are shown on a log scale as mean ± SEM. *p < 0.001 compared with young at same time point by two-way ANOVA; n = 8–20 individual animals per group at each time point. Data are cumulative of three to four replicate experiments at a given time point.

![FIGURE 2](http://www.jimmunol.org/)

**FIGURE 2.** Wound size at days 1–10 following cutaneous wound infection with *S. aureus*. (A) Representative images of wound from young (top panel) and aged (bottom panel) mice are days 1, 3, 7, and 10 after injury and infection. (B) Wound size expressed as percentage open wound area relative to time 0 at days 1, 3, 7, and 10 after cutaneous wound infection in young (filled circles and solid line) and aged (filled squares and dashed line) mice. The six wound from each animal were averaged to give one value for each animal; n = 7–15 individual animals per group at each time point. Data are shown as mean ± SEM. Data are cumulative of three replicate experiments at a given time point. *p < 0.05, **p < 0.01 compared with young at same time point by two-way ANOVA.
young mice. Following injury and infection, there were no age-dependent changes in the frequency of TLR2+ infiltrating macrophages and neutrophils (Fig. 3C, 3D). Moreover, aging did not alter the expression of TLR2 on infiltrating leukocytes after injury and infection (Table I). The changes in number of TLR2+ resident tissue macrophages with age may increase susceptibility to infection; however, following injury and infection, TLR2 expression did not contribute to prolonged bacterial infection in aged animals.

**Bacterial clearance is not affected by advanced age**

In addition to recognition of bacteria by the host immune system, neutrophils and macrophages that are recruited to the wound site are required to phagocytose and clear invading organisms. In particular, deficiencies in neutrophil and macrophage phagocytosis, as well as bactericidal potential, have been associated with reduced bacterial clearance as well as chronic or repeated infections (26, 44–46). A major phagocytic pathway in these cells is the FcγR

**FIGURE 3.** Expression of TLR2 by cutaneous neutrophils and macrophages. The number of neutrophils or macrophages expressing TLR2 was examined by flow cytometry. (A) Gating strategy for TLR2+ resident and infiltrating leukocytes. Live cells were gated on Gr-1 and F4/80: F4/80−Gr-1+ (neutrophils), F4/80+Gr-1− (macrophages). Neutrophil and macrophage populations were then evaluated for TLR2 positivity (solid black line). (B) Absolute number of TLR2+ macrophages in uninjured skin from young and aged mice. *p < 0.02 by Student t test; n = 7/group. (C) Frequency of TLR2+ wound macrophages at day 1 and day 3 in young (filled bars) and aged (open bars) mice. (D) Frequency of TLR2+ neutrophils at days 1 and 3 in young and aged mice. Data are shown as means ± SEM; n = 8–17 individual animals per group and are cumulative of three replicate experiments per time point. Data are not significant.
pathway (47). Interestingly, reduced expression of FcγRIII (CD16) and phagocytosis have been observed in neutrophils from aged humans (46). Similar studies in macrophage populations suggest a reduced phagocytic potential with advanced age (48–50). Thus, we sought to determine whether differences in phagocytosis and FcγRIII expression may contribute to delayed resolution of bacterial clearance in our model. Initially, we examined FcγRIII expression in peripheral blood neutrophils in our young and aged animals before and after infection. In line with studies by Butcher et al. (46) there was a reduction in the frequency of FcγRIII+ neutrophils in aged mice following injury and infection (Supplemental Fig. 1). Butcher et al. (46) had documented that reduced FcγRIII expression was associated with reduced phagocytic potential in neutrophils isolated from the periphery of elderly subjects. Interestingly, few studies have examined the impact of the wound microenvironment on phagocytic cell function in the setting of advanced age. Given these data, we examined the phagocytic potential and the expression of FcγRIII before and after phagocytosis in wound cells isolated from young and aged mice. Phagocytosis of pHrodo-S.

**FIGURE 4.** Wound neutrophil phagocytosis of *S. aureus* and FcγRIII expression. Wound leukocyte suspensions were allowed to phagocytose pHrodo-S. *aureus* particles for 0–60 min and then stained for FcγRIII expression. Phagocytosis and FcγRIII were assayed by flow cytometry. (A) Representative histograms (shaded gray, 4°C; control; black line, 37°C, 30 min; black dotted line, 37°C, 60 min) of phagocytosis by wound neutrophils (F4/80+/Gr-1+/TLR2+). (B) Percentage of wound neutrophils that phagocytosed pHrodo-S. *aureus* particles in young (filled bars) and aged (open bars) mice. Data are not significant. (C) Percentage of wound neutrophils expressing FcγRIII in young and aged mice. *p < 0.05 versus young control, †p < 0.001 versus young phagocytosis, ‡p < 0.05 versus young and aged controls by one-way ANOVA. (D) MFI of FcγRIII on wound neutrophils from young and aged mice. *p < 0.001 versus young control, †p < 0.001 versus young control and phagocytosis, ‡p < 0.001 versus aged matched control by one-way ANOVA. Data are shown as mean ± SEM; n = 9–12 individual animals per group for phagocytosis assays and are cumulative of 3 replicate experiments; n = 4–8 individual animals per group for FcγRIII studies and are cumulative of two replicate experiments.
To evaluate whether the observed reduction in FcγRIII impaired the ability of neutrophils to kill ingested organisms, isolated peripheral blood neutrophils were subjected to a modified bactericidal assay (52). Neutrophils were allowed to phagocytose opsonized pHrodo-\textit{S. aureus} for 15 min, and percentage killing of ingested bacteria was evaluated at 45 and 75 min after the end of the phagocytosis phase. No age-related differences in bactericidal activity were observed at either time point (Supplemental Fig. 2).

Aging impairs in vivo chemotaxis to dorsal cutaneous skin

Previously, our laboratory has demonstrated that peripheral blood neutrophils from aged animals demonstrate a basal hyperchemokinesis with a reduced directional migration toward a chemotatic stimulus in vitro (53). Given no difference in parameters of bacterial clearance, we extended these findings to determine whether age-related differences in leukocyte migration in vivo may contribute to heightened bacterial colonization and delayed wound closure in aged mice. Following s.c. injection of 100 pg KC, a potent neutrophil chemokine, and the murine homolog of human IL-8, neutrophil recruitment to the dorsal skin in aged mice was reduced as compared with young mice (Fig. 6, \( p < 0.05 \)). However, neutrophil recruitment in aged mice at a dose of 1000 pg was similar to that observed in young mice at a dose of 100 pg. These data suggest that aging impairs chemotaxis to cutaneous tissue with advanced age in response to a direct chemotatic stimulus.

Aging impairs in vivo chemotaxis to dorsal cutaneous skin

Previously, our laboratory has demonstrated that peripheral blood neutrophils from aged animals demonstrate a basal hyperchemokinesis with a reduced directional migration toward a chemotatic stimulus in vitro (53). Given no difference in parameters of bacterial clearance, we extended these findings to determine whether age-related differences in leukocyte migration in vivo may contribute to heightened bacterial colonization and delayed wound closure in aged mice. Following s.c. injection of 100 pg KC, a potent neutrophil chemokine, and the murine homolog of human IL-8, neutrophil recruitment to the dorsal skin in aged mice was reduced as compared with young mice (Fig. 6, \( p < 0.05 \)). To determine whether this could be overcome by higher doses of a chemotactic agent, we evaluated neutrophil recruitment after injection of 1000 pg KC. At a 10-fold higher dose, aged mice still had impaired neutrophil recruitment as compared with their younger counterparts given the same dose (Fig. 6, \( p < 0.05 \)). However, neutrophil recruitment in aged mice at a dose of 1000 pg was similar to that observed in young mice at a dose of 100 pg. These data suggest that aging impairs chemotaxis to cutaneous tissue with advanced age in response to a direct chemotatic stimulus.

Peak leukocyte infiltration is attenuated in aged mice

Once we established that neutrophil recruitment in aged mice was diminished in vivo in response to a lone chemotatic stimulus, we sought to determine whether we observed reduced leukocyte accumulation at the wound site in our model. Previous studies have documented that advanced age can alter the inflammatory cell infiltrate in noninfected wounds of aged mice (27, 29) as well as other tissues (54, 55); however, the impact of cutaneous infection on leukocyte recruitment with age has not been examined. Wound leukocyte recruitment was assayed by flow cytometry at days 1–7 after injury and infection (Fig. 7). At day 1, similar numbers of wound neutrophils and macrophages were observed in young and aged mice (Fig. 7A, 7B). However, at day 3, there was a reduction in neutrophil and macrophage numbers isolated from wounds from aged mice (Fig. 7A, 7B, $p < 0.05$). Numbers of wound neutrophils and macrophages were comparable in young and aged mice at day 7, despite persistent infection in aged animals. No difference in T cell recruitment was noted at any time point (Fig. 7C). The delay in neutrophil and macrophage recruitment at day 3 in aged animals may impair early bacterial clearance whereas the inability to recruit elevated numbers of leukocytes in aged mice at later time points may contribute to the persistent infection ob-

**FIGURE 7.** Time course of cutaneous leukocyte accumulation following injury and infection. Leukocyte infiltration to the wound and surrounding tissue area of young (filled bars) and aged (open bars) was assessed by flow cytometry at days 1–10 after cutaneous wound infection. (A) Absolute number of wound neutrophils. *$p < 0.01$ compared with young at same time point by two-way ANOVA. Data are shown as mean ± SEM; $n = 8–19$ per group at days 1–7, $n = 3–6$ at day 10. (B) Absolute number of wound macrophages. Data are shown as mean ± SEM; $n = 8–19$ individual animals per group at days 1–7, $n = 3–6$ individual animals per group at day 10. Data are cumulative of three to four replicate experiments at days 1–7 and are cumulative of two replicate experiments at day 10. (C) Absolute number of wound T cells. Data are shown as mean ± SEM; $n = 3–9$ individual animals per group and are cumulative of two replicate experiments. Data are not significant by two-way ANOVA.

**FIGURE 8.** Neutrophil and macrophage chemokine levels in wound homogenates. Neutrophil and macrophage chemokine levels in wounds of young (filled circles and solid line) and aged (filled squares and dashed line) mice present at the site of wound infection were measured by ELISA. (A) KC. *$p < 0.0001$ compared with young at same time point by two-way ANOVA. (B) MIP-2. *$p < 0.05$ compared with young at same time point by two-way ANOVA. (C) MCP-1. *$p < 0.05$ compared with young at same time point by two-way ANOVA. Data are shown as mean ± SEM; $n = 8–22$ individual animals per group (days 0–3) and $n = 3–6$ individual animals per group (day 7). Data are cumulative of three to four replicate experiments at days 0–3 and cumulative of two replicate experiments at day 7.
served in these animals. Moreover, this altered leukocyte recruitment may perturb wound healing kinetics, delaying transition from the inflammatory to the proliferative phase and ultimately impairing wound closure and restoration of the dermal matrix.

**Enhanced chemokine secretion in wounds from aged animals**

Important to neutrophil and macrophage recruitment are the chemotactic stimuli generated following tissue injury by keratinocytes and resident tissue leukocytes (56, 57). To determine whether the decreased neutrophil and macrophage numbers were due to reduced chemoattractant production, we evaluated the wound chemokine milieu. Interestingly, at day 1 following injury and infection, wounds from aged mice had elevated levels of neutrophil chemokines KC and MIP-2 (Fig. 8A, 8B, \( p < 0.05 \)). Furthermore, wounds from aged mice had increased levels of MCP-1, a chemokine that helps recruit and differentiate circulating monocytes (Fig. 8C, \( p < 0.05 \)). However, these elevated levels of neutrophil and macrophage chemokines were associated with similar neutrophil and macrophage recruitment at day 1. At day 3, when neutrophil and macrophage numbers were significantly reduced in aged animals, levels of these three chemotactic mediators were similar in young and aged mice (Fig. 8, \( p < 0.05 \)). In conjunction with reduced leukocyte accumulation, these findings paralleled our results observed following s.c. injection of KC, suggesting that a stronger chemotactic stimulus may be required to mediate a similar chemotactic response with advanced aged.

**Elevated CXCR2 expression in peripheral blood neutrophils of aged animals following injury**

KC and MIP-2 are ligands for the chemotactic receptor CXCR2 present on circulating neutrophils (58). Ligation of CXCR2 results in upregulation of selectins and integrins, which allow neutrophils to roll, adhere, and subsequently transmigrate across endothelial walls to reach the site of injury or infection (59–62). Considering a strong chemotactic stimulus was present at the wound site in aged

![Image](http://www.jimmunol.org/download/1753.pdf)
animals, we examined the peripheral neutrophil pool to determine whether age-dependent differences in CXCR2 expression could account for reduced leukocyte recruitment with age. Following injury and infection at days 1 and 3, the frequency of neutrophils in circulation was elevated in aged mice compared with young mice at both time points (Fig. 9A, 9B, \( p < 0.05 \)). There was no difference in the frequency of CXCR2+ neutrophils between young and aged mice prior to or following injury (Fig. 9C). Following cutaneous wound infection, downregulation of CXCR2 expression was observed in mice of both age groups; however, the MFI of CXCR2 on neutrophils from aged mice was significantly elevated (Fig. 9D). This elevation persisted out to day 3, where CXCR2 expression remained increased in aged mice relative to young mice. These data suggest that mediators downstream of CXCR2 may contribute to decreased neutrophil recruitment to the wound site in aged animals.

**ICAM-1 is reduced in infected wounds from aged mice.**

In addition to the role of KC and MIP-2–mediated neutrophil up-regulation of selectins and integrin via CXCR2, secretion of these chemokines as well as proinflammatory cytokines such as TNF-\( \alpha \) promote upregulation of adhesion molecules such as ICAM-1 on vascular endothelial cells to promote rolling and firm adhesion of neutrophils along the vascular endothelium (63–65). Perturbation of the upregulation of adhesion molecules would impair neutrophil adherence and diapedesis into the infected wound tissue. Thus, we hypothesized that ICAM-1 may fail to be upregulated in aged mice as compared with young mice (Fig. 10). Prior to wound infection, levels of ICAM-1 were comparable between young and aged mice. Following *S. aureus* wound infection at day 1, levels of ICAM-1 trend downward in both age cohorts. Interestingly, at day 3 when neutrophil and macrophage recruitment is significantly reduced in aged mice, levels of ICAM-1 are reduced in aged mice as compared with young mice (Fig. 10, \( * p < 0.05 \)). These data suggest that decreased ICAM-1 in aged mice may contribute to reduced neutrophil trafficking into tissue. Moreover, elevated levels of chemokines such as KC and MIP-2 in the absence of relative increases in ICAM-1 suggest that there may be a dysregulation of the signaling pathways in endothelial cells that act to upregulate ICAM-1 in response to these chemokines.

**Discussion**

In review, we have developed a murine model of cutaneous wound infection with *S. aureus* that demonstrates elevated bacterial colonization and delayed wound closures in aged mice at early time points, which persists out to day 10 after wound infection. These findings parallel clinical observations in elderly patients with elevated *S. aureus* infection rates and prolonged, costly hospital stays (2, 25, 34). Other murine models of infection, such as pneumonia, also report an increased bacterial burden in aged animals (66). Moreover, we observed that wound closure was protracted in aged animals. Studies in murine models of uninfected wounds report similar delays in wound closure with advanced age (28, 29, 67); however, the time to closure was reduced as compared with infected wounds from our animals.

An important factor in mediating the host response to infection is early recognition of foreign pathogens by host immune cells by pathogen-associated molecular patterns via pattern recognition receptors such as TLR2 (68). Loss of TLR2 or MyD88, a mediator of TLR signaling, has been associated with increased susceptibility to *S. aureus* infection and heightened levels of *S. aureus* bacteremia (40, 42, 43, 69). In our model, we observed an age-dependent decrease in the absolute number of TLR2+ resident tissue macrophages, but no differences in expression or frequency of TLR2+ infiltrating wound neutrophils or macrophages were observed. Studies demonstrate variable reduction of TLR macrophage expression with age (55, 66, 70), whereas previous studies from our own laboratory have demonstrated no change in peritoneal or splenic macrophage TLR2 and TLR4 expression (71). In circulating neutrophil populations, human studies suggest that expression of TLR2 and TLR4 are unaltered with age, although membrane-associated MyD88 was decreased with age exogenous stimulation with LPS (11). Although not evaluated in our study, age-associated alterations in TLR2 signaling pathways, such as MyD88, may dampen TLR2 responses in aged individuals and contribute to delayed resolution of bacterial infection (72–74).

Previous studies have reported that aging negatively impacts the ability of both neutrophils and macrophages to phagocytose pathogens (26, 27, 46, 48, 49), although few studies have evaluated the phagocytic potential of leukocytes following recruitment in response to tissue injury. Furthermore, FcγRs have been shown to modulate phagocytosis (75, 76) and reduced FcγRIII expression in circulating human neutrophils from elderly donors was correlated with impaired phagocytosis (46). Given that our observed differences in FcγRIII did not contribute to functional changes in FcγRIII-dependent phagocytosis or bactericidal activity, we did not further evaluate additional phagocytic mechanisms and pathways. However, that lack of age-related differences in neutrophil phagocytosis is in concert with other murine studies that do not recapitulate the phagocytosis deficits observed in circulating human neutrophils (55). Our study extends these findings in rodent studies, demonstrating that neutrophil phagocytosis is not impaired by advanced age following recruitment to a specific tissue microenvironment.

We next chose to examine whether age-associated alterations in chemotaxis could contribute to impaired resolution of wound infection in our aged mice, as previous studies highlight reduced migration of peripheral blood neutrophils isolated from healthy, elderly humans and mice (11, 29, 54, 55, 77). Specifically, following sterile cutaneous wound injury, neutrophil peak infiltration has been shown to be attenuated in aged C57BL/6 mice as compared with young mice (29). This parallels studies of oral infection with *Salmonella typhimurium* (54) or peritoneal challenge with *Candida albicans* (55), where aged mice demonstrated reduced neutrophil chemotaxis to these respective compartments. Alternatively, neutrophil trafficking to the lung after trauma or environmental insults is enhanced with age, highlighting the unique and delicate microenvironment of the aging lung (18, 78, 79).

**FIGURE 10.** ICAM-1 levels in wound homogenates. ICAM-1 levels in wounds of young (filled bars) and aged (open bars) mice present at the site of wound infection were measured by ELISA. Data are shown as mean ± SEM; \( n = 8–12 \) individual animals per group. Data are cumulative of two replicate experiments. \( * p < 0.05 \) versus young at same time point by two-way ANOVA.
Recently, we reported that peripheral blood neutrophils from unmanipulated young and aged mice have a basal hyperchemokinesis but lack directional migration ex vivo in response to KC (53). We extend these findings to show that at increasing doses of KC in vivo, neutrophils from aged mice had a diminished migratory response to cutaneous tissue as compared with young mice. These data mirrored neutrophil recruitment in response to cutaneous S. aureus wound infection in our model, as elevated levels of neutrophil chemokines were required to mediate a similar chemotactic response in aged mice as compared with young mice. This reduction in neutrophil accumulation was associated with delayed resolution of wound infection in our aged animals. Clinically, patients with reduced neutrophil function or numbers are at a heightened risk for chronic and repeated infections with catalase-positive bacteria, such as S. aureus (44, 45, 80). However, the accepted dogma of efficient wound healing implies that gratuitous neutrophil accumulation can result in excessive reactive oxygen species and elastase production, exacerbating tissue damage and impeding wound healing (5, 81). Wound healing models using fetal or young mice show that a paucity of neutrophil recruitment is correlated with reduced scar formation (82, 83) and that neutrophil depletion may accelerate aseptic wound closure (84). Despite these findings, studies in the literature on aging have demonstrated that even in the setting of sterile wound healing, ablation of the neutrophil population delays wound closure in aged animals (29). Importantly, increasing neutrophil numbers via i.p. administration of G-CSF enhanced rates of wound closure in aged mice to those observed in young mice (29). In the context of an infected wound, the necessity of neutrophil recruitment becomes increasingly paramount. Thus, the decreased absolute numbers of neutrophils and macrophages in our model may not only contribute to bacterial colonization differences observed with age, but they may also play a role in delayed wound resolution in aged animals.

Although we saw blunted chemotaxis to the CXCR2 ligand KC, we observed elevated CXCR2 expression on circulating neutrophils from aged animals, suggesting that despite adequate expression of CXCR2, mediators of CXCR2 signaling may be impaired with age. For example, recruitment of β-arrestin 2 to CXCR2 has been shown to be required for CXCR2 activation (60) and has been reported to be decreased in brain tissue of elderly humans (85). Others have documented that high levels of KC promote CXCR2 receptor desensitization and impaired chemotaxis (86). Thus, it is plausible that the early peak in KC levels observed in aged mice acts to attenuate neutrophil recruitment despite persistent infection in our aged animals. Moreover, we demonstrate that ICAM-1 expression is reduced at day 3 in aged mice as compared with young mice. ICAM-1 is critical in neutrophil adhesion and subsequent transmigration from the vasculature to the target tissue. Previously we have shown that following burn trauma, lung endothelial ICAM-1 is elevated and associated with prolonged neutrophilia in lungs from aged mice as compared with young mice (53). The differences between these studies are likely attributable to different models of injury and the unique microenvironment of the lung as discussed previously.

Given these data, it is reasonable to suggest that enhancing neutrophil recruitment in aged mice may reduce bacterial colonization and wound closure. Interestingly, G-CSF is not only an important factor in granulocyte development in the bone marrow and survival in circulation (87–89), but it also serves to enhance CXCR2-mediated chemotaxis (90, 91), improve integrin–adhesion molecule interactions (92), and upregulate ICAM-1 (93). Specifically, G-CSF has been shown to upregulate CXCR2 via STAT3, enhance signaling downstream of CXCR2 (90), restore chemotactic defects observed in aged rats (77), induce endothelial ICAM-1 expression (93), and promote neutrophil adhesion to ICAM-1 (92, 94). Taken together, these suggest a plausible interconnection between G-CSF, CXCR2, and ICAM-1, and elucidating these interactions may provide insight and novel therapeutic approaches to age-related impaired chemotaxis and immune cell dysfunction. However, caution should be taken when considering altering the distribution of leukocytes, in particular in the elderly, as they are highly susceptible to pneumonia.

Because bacterial strains, in particular S. aureus, continually evade our current antibiotic treatments, understanding how advanced age impairs the host immune response may allow us to target immunomodulatory mechanisms that will improve outcomes following cutaneous wound injury in elderly patients. Future work examining methods to enhance leukocyte migration to the wound bed, such as local or systemic growth factors, may allow for modulation of the host immune system to enhance its response to invading pathogens following tissue injury in immunocompromised patients.
