Psoriasis is a common immune-mediated skin disorder whose complex pathophysiology involves environmental factors, including microbes, as well as host susceptibility factors, including genetically determined immunologic propensities (1, 2). Recent genome-wide association studies have highlighted potential roles of specific proteins in disease pathogenesis, including HLA-C, IL-12, IFN-α, and IL-23R (3). Some of these polymorphisms are also linked to therapeutic responses of psoriasis patients to specific therapies (4). These findings emphasize the immunologic nature of psoriasis and implicate specific immune functions, such as HLA-C–mediated Ag presentation and IL-12/IL-23–dependent innate immune signals. Because innate immune cells such as dendritic cells (DCs) are outstanding APCs, and because IL-12 and IL-23 are secreted by innate immune cells to amplify T cell activation and differentiation events, these genetic clues suggest that aberrant DCs and T cell functions are integral to psoriasis.

TNIP1, which encodes the ABIN-1 protein, is strongly linked to psoriasis in both European (combined genome-wide p value of $1 \times 10^{-20}$) and Chinese (combined genome-wide p value of $3.8 \times 10^{-21}$) populations (5–7). ABIN-1 restricts several NF-κB signaling cascades and regulates cell survival (8–12). In vitro studies suggest that ABIN-1 can bind NEMO/IKKγ and inhibit TNF-induced NF-κB signaling (13). ABIN-1 can also bind ubiquitin chains, and ubiquitin binding by ABIN-1 is important for the ability of ABIN-1 to restrict TNF and TLR signals (11, 12). Global loss or mutation of ABIN-1 leads to either embryonic lethality or spontaneous inflammation and autoimmunity (11, 12, 14). These studies indicated that ABIN-1 plays critical roles in regulating TNF and TLR signals. However, the mechanisms by which ABIN-1 regulates physiological immune homeostasis and psoriasis susceptibility are unknown.

DCs have long been recognized as important cells for triggering immune responses during overt immunizations or infections (15). Recent studies suggest that DCs also preserve immune homeostasis under basal conditions (16–21). DCs may regulate susceptibility to psoriasis by secreting type I IFNs, TNF, or other proinflammatory cytokines, as well as by stimulating skin T cells (22). Given the potential importance of DCs to immune homeostasis in the skin and the potential importance of ABIN-1 polymorphisms to psoriasis, we have
investigated whether ABIN-1 expression in DCs may regulate psoriasis susceptibility.

Materials and Methods
Mice
The initial targeting of the Tnip1 (ABIN-1) gene in C57BL/6N PRX-B6T embryonic stem cells was previously described (11). ABIN-1–targeted embryonic stem cells were transfected with an EF1α-Cre expression construct (20), and colonies were screened for deletion of the neomycin gene and retention of ABIN-1 exons 12–15 flanked by LoxP sites (floxed allele). Genotypes were confirmed both by Southern blot analyses and by PCR (primers: 5’-TGTATTCCCCCTTGCCCCATCAGC-3’, 5’-GTTAACAGGGGCAC-TCCAGG-5’, and 5’-ATGGGTTGGTATGGGATAGG-3’). MyD882 mice were described previously (23). All mouse experiments were approved by the University of California, San Francisco Institutional Care and Use Committee.

Cell preparation and analyses
Cell preparations and flow cytometric analyses were performed as previously described (20). Immunoblots were performed as described (11). Abs to surface markers (BD Biosciences), actin (Calbiochem), phospho-1Bki, IκBα, phospho-Erk, Erk, phospho-JNK, and JNK (Cell Signaling Technologies) were purchased.

Imiquimod treatment and scoring of skin inflammation
Imiquimod (IMQ) treatments were performed largely as previously described (24, 25). Mice received a daily topical dose of 12.5 μg IMQ cream (5%) (Perrigo) or lotion control for 12 consecutive days. Skin inflammation was scored using a previously described scoring system (24). Histological sections were prepared by the University of California, San Francisco Veterans Affairs Medical Center Pathology Core.

Results and Discussion
To investigate whether ABIN-1 expression in DCs regulates immune functions in vivo, we generated mice bearing LoxP sites flanking exons 12–15 of ABIN-1 (ABIN-1Δ) mice and bred them with CD11c-Cre transgenic mice to create mice lacking ABIN-1 in DCs (Supplemental Fig. 1A) (26). ABIN-1fl/fl CD11c-Cre mice appeared grossly normal for up to 6 mo of age. Conventional DCs (cDCs; CD11clMHC class II+) and plasmacytoid DCs (pDCs; CD11cbB220hi) were present in slightly elevated numbers in spleens from ABIN-1fl/fl CD11c-Cre mice (Fig. 1A). These cells expressed relatively normal levels of activation markers, with the exception of minimally elevated levels of CD40 on cDCs and slightly lower CD80 levels on pDCs (Supplemental Fig. 1B, 1C). Thus, ABIN-1 expression in DCs is not required for DC development but modestly regulates DC activation under basal conditions. ABIN-1fl/fl CD11c-Cre mice developed splenomegaly and lymphadenopathy by 3–4 mo of age, accumulating myeloid (CD11b+Gr-1+) and lymphoid immune phenotype T cells (Fig. 1B–D and data not shown). Thus, ABIN-1 expression in DCs preserves myeloid and lymphoid immune homeostasis.

DCs are activated by TLR ligands during overt immunizations and infections and may also respond to MyD88-dependent signals under basal conditions (20). We asked whether ABIN-1 preserves immune homeostasis by restricting MyD88-dependent signals in DCs by generating compound ABIN-1fl/flMyD882/2 CD11c-Cre mice that lack both ABIN-1 and MyD88 specifically in DCs. Remarkably, in contrast to ABIN-1fl/fl CD11c-Cre mice, the spontaneous accumulation of myeloid cells and activated T lymphocytes observed in ABIN-1fl/fl CD11c-Cre mice was abrogated in ABIN-1fl/flMyD882/2 CD11c-Cre mice (Fig. 2, Supplemental Fig. 2A, 2B). Thus, ABIN-1 restricts basal Myd88-dependent intracellular signals in DCs, thereby preserving immune homeostasis in unperturbed mice.

To determine how ABIN-1 restricts MyD88-dependent signals in DCs, we tested the responses of ABIN-1+/+ and ABIN-1+/− bone marrow–derived BMDCs (BMDCs) to the TLR4 ligand LPS. LPS-stimulated ABIN-1+/− BMDCs secreted more TNF, IL-6, IL-12, and IL-23 than did control BMDCs (Supplemental Fig. 2D). This is consistent with...
a recent report showing that ABIN-1 restricts TLR-induced IL-6 and TNF (12). Importantly, our current study implicates ABIN-1 in restricting IL-23 production by DCs. After LPS stimulation, ABIN-1<sup>2/2</sup> BMDCs also exhibited exaggerated NF-κB, JNK, and p38 (but not ERK) signaling when compared with control BMDCs (Supplemental Fig. 2C). Hence, ABIN-1 regulates TLR responses in DCs by restricting TLR-induced NF-κB and MAPK signals.

Given the genetic linkage of ABIN-1 to psoriasis and the exaggerated production of IL-12 and IL-23 by ABIN<sup>2/2</sup> DCs, we asked whether ABIN-1 expression in DCs regulates susceptibility to experimental psoriasis. Topical treatment with the TLR7 ligand IMQ can cause a psoriasis-like condition in humans and causes similar lesions in mice. This is now an experimental psoriasis. (A) Clinical skin inflammation scores in the indicated genotypes of mice at the indicated days of IMQ treatment. (B) H&E-stained sections of back skin of mice of indicated genotypes after treatment. Epithelial layer denoted by brackets and “epi.” Note that skin inflammation in ABIN<sub>1</sub><sup>fl/fl</sup>MyD88<sup>+/+</sup> mice is abrogated in ABIN<sub>1</sub><sup>fl/fl</sup>MyD88<sup>fl/fl</sup> mice. All mice are CD11c-Cre<sup>+</sup>. Error bars represent SD. *p < 0.05 by Student t test. Scale bar, 0.1 mm. Data are representative of three independent experiments.

FIGURE 3. ABIN-1 restricts IMQ responses in DCs and prevents experimental psoriasis. (A) Clinical scores of IMQ-induced skin inflammation in ABIN<sub>1</sub><sup>1/4</sup> CD11c-Cre<sup>+</sup> and ABIN<sub>1</sub><sup>+/+</sup> CD11c-Cre<sup>+</sup> (control) mice at indicated days of IMQ treatment. (B–G) H&E-stained sections of back skin of mice of indicated genotypes from areas treated with IMQ. Epidermal layer (epi) is indicated by brackets (B–G). Epidermal hyperplasia (thickening of epidermal layer) is evident in ABIN<sub>1</sub><sup>1/4</sup> mice (C, E, G) compared with ABIN<sub>1</sub><sup>+/+</sup> mice (B, D, F). In (C), (E), and (G), open arrows show hyperkeratotic scaling. In (E), broad areas of hypogranulosis (abnormal loss of purple keratohyaline granules in the skin’s granular layer) are indicated by closed arrows. In (G), neutrophils (blue arrow) and parakeratosis (abnormal retention of nuclei in the outermost layer of skin, green arrow) are shown in Munro’s microabscess (dotted boxed area). Scale bar, 0.1 mm for (D–G). Scale bar, 0.5 mm for (B) and (C). (H) ELISA and multiplex Luminex analyses of cytokine production from BMDCs after treatment with the indicated doses of IMQ. (I) Numbers of CD3<sup>+</sup> and CD4<sup>+</sup> T cells from skin-draining lymph nodes from IMQ-treated mice of indicated genotypes. Distinct Th2 (CD4<sup>+</sup>IL-4+) populations were not detected. All mice in (A)–(G) and (I) are CD11c-Cre<sup>+</sup> radiation chimeras. All data are representative of three to seven independent experiments. Error bars represent SD. *p < 0.05 by Student t test.
established mouse model of psoriasis (24, 27). To investigate the functions of radiation-sensitive DCs, we generated radiation chimera bearing hemopoietic stem cells from ABIN-1fl/fl CD11c-Cre or ABIN-1+/+ CD11c-Cre mice. Treatment of mice with IMQ caused markedly increased erythema, scaling, and skin thickening in ABIN-1+/+ CD11c-Cre chimera, which combine to yield increased composite psoriasis scores in ABIN-1+/+ CD11c-Cre mice compared with control chimera (Fig. 3A). Histologic examination of skin sections from these mice revealed epidermal hyperplasia, hypogranulosis, hyperkeratosis, and parakeratosis with neutrophils—all stereotypical histologic findings of human psoriasis—in ABIN-1+/+ CD11c-Cre mice but not in control mice (Fig. 3B–G). Treatment of mice with a topical emollient as control did not lead to significant clinical responses. Hence, ABIN-1 expression in DCs prevents susceptibility to experimental psoriasis.

IMQ-induced psoriasis involves IL-17–dependent production of IL-17 (24). We thus measured the levels of inflammation in DCs prevents susceptibility to experimental psoriasis. Treatment of mice with a topical emollient as control did not in ABIN-1fl/fl CD11c-Cre mice but not in control mice (Fig. 3B–G). These mice revealed epidermal hyperplasia, hypogranulosis, hyperkeratosis, and parakeratosis with neutrophils—all stereotypical histologic findings of human psoriasis—in ABIN-1+/+ CD11c-Cre mice compared with wild-type DCs, whereas IL-12p40 levels were similar (Fig. 3H). We next tested the induction of IL-17 expression in IMQ-treated mice. Whereas the total numbers of T cells in skin-draining lymph nodes were similar in ABIN-1+/+ CD11c-Cre and ABIN-1+/+ CD11c-Cre chimera, increased numbers and percentages of CD4+ Th17 cells were observed in ABIN-1+/+ CD11c-Cre mice (Fig. 3I). Many IL-17–producing T cells in IMQ-treated mice are epidermal TCRγδ+ T cells (28). Consistent with this notion, increased percentages and numbers of TCRγδ+ T cells were noted in draining lymph nodes from ABIN-1+/+ CD11c-Cre mice (Fig. 3I). In contrast, analyses of the skin-draining lymph nodes from IMQ-treated ABIN-1+/+ CD11c-Cre mice showed approximately normal Th1 (IFN-γ+) cell numbers and no significant numbers of Th2 (IL-4+) cells (Fig. 3I and data not shown). Finally, consistent with the role of IL-17 in supporting neutrophil recruitment, ABIN-1+/+ CD11c-Cre mice contained increased epidermal neutrophil microabscesses (Fig. 3G). Thus, ABIN-1 expression in DCs restricts IL-23 secretion, Th17 cell differentiation, neutrophilic inflammation, and psoriatic lesions after IMQ treatment.

To determine whether ABIN-1–dependent regulation of MyD88-dependent signals in DCs was integral to disease pathogenesis, we tested the IMQ responses of chimera generated from ABIN-1+/+ MyD88+/+ CD11c-Cre compound mutant and control hemopoietic stem cells. Double mutant ABIN-1+/+ MyD88+/+ CD11c-Cre mice exhibited much less psoriasis than did ABIN-1+/+ CD11c-Cre mice (Fig. 4A). Indeed, ABIN-1+/+ MyD88+/+ CD11c-Cre mice exhibited similar clinical responses to MyD88+/+ CD11c-Cre and wild-type chimera (Fig. 4A, Supplemental Fig. 2E). Histological studies confirmed the reduced inflammation observed in ABIN-1+/+ MyD88+/+ CD11c-Cre mice compared with ABIN-1+/+ CD11c-Cre mice (Fig. 4B). Thus, ABIN-1–dependent regulation of MyD88-dependent signals in DCs regulates susceptibility to experimental psoriasis.

Our findings indicate that ABIN-1 restricts MyD88-dependent signals in DCs. ABIN-1 expression in DCs restricts TLR-induced NF-κB and JNK signals, thereby limiting DC expression of IL-23 and other cytokines. IL-23 supports the accumulation of IL-17– and IL-22–producing T cells. IL-17 induces epidermal neutrophil infiltration, and IL-22 alters keratinocyte proliferation and differentiation. Thus, exaggerated IL-23 expression likely leads to characteristic dermal lesions of psoriasis (29). Our studies mechanistically link ABIN-1, a major psoriasis susceptibility gene, with IL-23x and IL-23R, two other major psoriasis susceptibility genes. This linkage suggests that ABIN-1 and IL-23–dependent inflammation may be part of a common dominant pathophysiological pathway leading to psoriasis. These cellular and molecular insights into how ABIN-1 prevents psoriasis provide mechanistic insights for the genetic suggestions about psoriasis pathophysiology. Moreover, mice bearing ABIN-1 mutations should be extremely valuable models for studying psoriasis pathophysiology and treatment.
