Proteasome Inhibition with Bortezomib Depletes Plasma Cells and Specific Autoantibody Production in Primary Thymic Cell Cultures from Early-Onset Myasthenia Gravis Patients

Alejandro M. Gomez,* Nick Willcox,†,1 Kathleen Vrolix,* Jonas Hummel,* Gisela Nogales-Gadea,*,† Abhishek Saxena,* Hans Duime,§,¶ Fons Verheyen,§,¶ Peter C. Molenaar,* Wim A. Buurma,* Marc H. De Baets,* Pilar Martinez-Martinez,*1 and Mario Losen*1

Bortezomib is a potent inhibitor of proteasomes currently used to eliminate malignant plasma cells in multiple myeloma patients. It is also effective in depleting both alloreactive plasma cells in acute Ab-mediated transplant rejection and their autoreactive counterparts in animal models of lupus and myasthenia gravis (MG). In this study, we demonstrate that bortezomib at 10 nM or higher concentrations killed long-lived plasma cells in cultured thymus cells from nine early-onset MG patients and consistently halted their spontaneous production not only of autoantibodies against the acetylcholine receptor but also of total IgG. After bortezomib treatment, they showed ultrastructural changes characteristic of endoplasmic reticulum stress after 8 h and were no longer detectable at 24 h. Bortezomib therefore appears promising for treating MG and possibly other Ab-mediated autoimmune or allergic disorders, especially when given in short courses at modest doses before the standard immunosuppressive drugs have taken effect. The Journal of Immunology, 2014, 193: 1055–1063.

Myasthenia gravis (MG) with Abs against the muscle acetylcholine receptor (AChR) is one of the best understood of the numerous autoimmune neurologic diseases now recognized (1). It is generally agreed that the patients’ autoantibodies are pathogenic, as they decrease AChR numbers by antigenic modulation and complement-mediated damage (2, 3). Patients with early-onset MG (EOMG; before 45 y of age) are an unusually well-defined subgroup, with strong female and HLA-B8 biases (4) and characteristic lymph node–like infiltrates in the thymic medulla (5–7).

Treatment of MG relies primarily on glucocorticoids, often combined with broad-spectrum immunosuppressants such as azathioprine, mycophenolate mofetil, or rituximab (8). However, their efficacy and side effects vary greatly between patients, and they reduce autoantibody titers and restore muscle strength only after delays as long as 4–15 mo (9, 10). Additionally, drug-resistant AChR MG patients treated with rituximab (anti-CD20) showed no reduction in either AChR Ab titers or IgG levels, despite complete elimination of circulating B cells (10). In such patients, long-lived plasma cells, which are CD20−, are likely to be the main producers of the autoantibodies. Moreover, they are probably responsible for the delayed responses of most MG patients to immunosuppressants, which mainly act by preventing generation of new plasma cells from B cells and by impairing the activation and proliferation of Th cells (11–13).

Plasma cells are high-rate Ab-secreting cells (>10,000 molecules/cell/second) (14, 15). They are terminally differentiated and do not divide. Among the B cell lineage, they are uniquely radioresistant. Whereas some are short-lived, others persist for many months (or even years) (16) in special survival niches in bone marrow (17) and lymphoid tissues (18). They are the main producers of circulating IgG and are clearly key players in chronic Ab-mediated autoimmune diseases. Their resistance to both standard immunosuppressants and rituximab therefore necessitates a different pharmacological approach.

Many recent studies have focused on drugs that target the neoplastic plasma cells in multiple myelomas (MMs). Partly because of their high rate of protein synthesis and dependence on protective unfolded protein responses, MM cells are very susceptible to proteasome inhibitors (19). These rapidly induce apoptosis by activating the terminal unfolded protein response (20) and inhibiting the transcription factor NF-κB (21). Proteasome
2–3 d we removed (and stored) 90 mm Alkmaar, the Netherlands), 50 U/ml penicillin, 50 U/ml streptomycin, and thymic cell suspensions were washed (and some aliquots irradiated). Cell culture and experimental design

Fresh in Maastricht, the Netherlands, in 2013, again after mechanical and thymectomy. Subsequently, they were thawed carefully and cultured at 6 × 10^5 to 1 × 10^6 cells per well in 96-well round-bottom plates, without added stimulants, in 200 μl RPMI 1640 medium containing 15% PBS (Bodico, Alkmaar, the Netherlands), 50 U/ml penicillin, 50 U/ml streptomycin, and 1 mM sodium pyruvate at 37°C in humidified air with 5% CO2. Every 2–3 d we removed (and stored) 90 μl supernatant from each well and replaced it with 100 μl fresh medium with and without any test drugs. Thymic cells were precultured for 3–7 d to allow recovery from the thawing procedure, adaptation to culture conditions, and for measuring baseline Ab production before addition of test drugs.

We dissolved lyophilized bortezomib (Velcade; Janssen-Cilag, Belgium) in sterile saline, dexamethasone (D4902; Sigma-Aldrich) in absolute ethanol, and lenalidomide (Santa Cruz Biotechnology; sc-218656) in dimethyl sulfoxide.

Autoantibody and total IgG assays

In a standard radioimmunoprecipitation assay, we incubated 20 μl culture supernatant overnight at 4°C with 12.5 μl TE671 human rhabdomyosarcoma cell membrane extract (containing ~3 fmol human AChR). The AChR was labeled with excess [125I]Tx-bungarotoxin (NEX126, 3.4 TBq/ mmol; PerkinElmer), and normal human serum was used as carrier. Any immune complexes were precipitated by addition of 150 μl goat anti-human IgG and incubation for 4 h at 4°C. We also used a standard curve after assaying serial dilutions of the anti-AChR mAb 637 (36) in parallel. Results are expressed as nanomoles of IgG-bungarotoxin binding sites per liter of culture medium per day, normalized as the percentage of those in untreated cultures.

We measured total IgG in the diluted culture supernatants with a standard sandwich ELISA as described (26), capturing with goat F(ab')2; anti-human IgG-Fcγ (109-006-008; Jackson ImmunoResearch Laboratories; diluted 1:200) and detecting with HRP-conjugated goat F(ab')2; anti-human IgG-Fcγ (109-036-008; Jackson ImmunoResearch Laboratories; diluted 1:2,000). Results were expressed as nanograms total IgG secreted per milliliter supernatant per day, normalized as above. The newly synthesized AChR Ab and total IgG were quantitated as their present concentrations (in 200 μl) minus the concentration in the previous sample (in 100 μl) divided by the time interval.

Immunofluorescence staining and enumeration of plasma cells by microscopy

Cultured cells (5 × 10^4 to 5 × 10^5) were cytocentrifuged onto poly-L-lysine-coated slides (for 5 min at ~120 g; Cyto-Tek centrifuge model 4332; Sakura Finetek, Tokyo, Japan). Slides were air-dried for 1 h at 22°C and then fixed in 4% paraformaldehyde at 4°C for 10 min. Subsequently, they were blocked with 2% BSA in PBS and incubated with Hoechst 33342 solution (2 μg/ml; Sigma-Aldrich, catalog no. B2261) to stain DNA. We stained for plasma cells with mouse anti-human CD138 mAb (1:250, clone MI15; Dako), donkey anti-mouse IgG Alexa 594 (1:300, A21203; Molecular Probes/Invitrogen), and goat anti-human IgG Alexa 488 (1:500, A11013; Molecular Probes/Invitrogen). Slides were mounted in 80% glycerol-TBS and stored at 4°C in the dark. All washing and incubation steps were performed with TBS–Triton X-100 (0.03%). We counted the plasma cells from each well, in a blinded fashion, on a fluorescence microscope (Olympus BX51), identifying them by their distinctive size, shape (extensive cytoplasm and eccentric nucleus), and positive staining for internal IgG and/or surface CD138. Absolute numbers of plasma cells per well are given in Table II and shown in the figures as the percentage of those in untreated cultures. Total numbers of recovered cells were measured by automated counting of trypan blue–excluding cells (Bio-Rad TC20 automated cell counter).

FACS analysis of B, T, and plasma cells and membrane integrity

For B and T lymphocyte identification, cells were incubated for 30 min at 4°C with 30 μl of a FACS buffer (2% FCS, and 0.1% sodium citrate in PBS) mouse anti-human CD3 (BD Biosciences, 555339) and PE mouse anti-human CD19 (BD Biosciences, 555413), all diluted 1:100 in FACS buffer. The samples were washed twice, kept at 4°C in the dark, and analyzed within 2 h. Dead cells were identified by propidium iodide (PI) counterstaining (BD Biosciences apoptosis detection kit).

To identify plasma cells, we incubated cells for 15 min at 22°C in the dark, with the following mix of anti-human mAbs: CD138-PE (IBL, M2287; 1:25), CD19-PerCy5.5 (BD Biosciences, 554723). We used either a FACSCalibur (for B and T cells) or a FACS-Canto II (for plasma cells), plus CellQuest software (all from BD Biosciences, 560365; 1:20), and CD45-V500 (BD Biosciences, 560777; 1:20).

Materials and Methods

Patients

The EOMG patients’ clinical information is shown in Table I. Thymus tissue was obtained with their informed consent and Ethics Committee approval. None of the patients had been pretreated with glucocorticoids; otherwise, they were selected only because of high serum anti-AChR titers, the correspondingly high productivity of these Abs by their thymic cells in nonpregnant MM patients and appears relatively safe. Lenalidomide inhibits the proliferation of several MM cell lines and disrupts the stromal support in their survival niches (28). Because it reduces IgM and IgG responses to PWM (29), it must affect earlier B lineage cells too.

In most EOMG patients, the thymic infiltrates include numerous germinal centers (5–7), many of them ACHR-specific, and autoreactive T and B cells along with terminal plasma cells (30). In our experience, some degree of thymic hyperplasia is observed in >80% of steroid-naive EOMG patients (30, 31). In primary cultures of cells from EOMG, but not from control thymi, autoreactive plasma cells spontaneously secrete AChR autoantibodies, with titers and epitope specificities very similar to those in the patients’ sera (30, 31). They do so for several weeks (at least), even after irradiation (31), implying that many of them are long-lived. This longevity and radiation resistance contrasts strikingly with most thymic subsets, for example, immature thymocytes and T cells, which have a very high turnover in vivo (32, 33) and die rapidly in culture (31, 34).

Thymectomy is part of standard management of EOMG in many centers (5–7). Thus, the tissue removed is an almost uniquely accessible source of long-lived human autoimmune plasma cells. In the present study, we have used it to test their susceptibility to drugs, as assessed by their ultrastructure and production of IgG and AChR autoantibodies. We demonstrate that very low concentrations of bortezomib are cytotoxic for total and autoimmune human plasma cells, and thereby prevent production and release of autoantibodies, whereas lenalidomide and dexamethasone have little effect.

Cell culture and experimental design

Thymic cells were cultured as described (35). Briefly, enzymatically dispersed thymic cell suspensions were washed (and some aliquots irradiated with 1250 rad from a 60Co source) and cryostored within a few hours of thymectomy. Subsequently, they were thawed carefully and cultured at 6 × 10^3 to 1 × 10^6 cells per well in 96-well round-bottom plates, without added stimulants, in 200 μl RPMI 1640 medium containing 15% PBS (Bodico, Alkmaar, the Netherlands), 50 U/ml penicillin, 50 U/ml streptomycin, and 1 mM sodium pyruvate at 37°C in humidified air with 5% CO2. Every 2–3 d we removed (and stored) 90 μl supernatant from each well and
sciences) for data acquisition, and we analyzed results using the Flowing software (version 2.5.1; Turku Center for Biotechnology, Turku, Finland). Samples were gated to exclude cell debris and aggregates; at least 10,000 events per sample were measured for B and T cell analyses, and 150,000 events for plasma cells. Results are expressed as the absolute number of cells per well, normalized as the percentages of B, T, and total viable cells in untreated cultures.

**Electron microscopy**

Cultured thymic cells were collected, pelleted (7 min, 220 × g, 4°C) and fixed with 3% glutaraldehyde plus 1.4% sucrose buffered in 0.09 M KH2PO4 at pH 7.4. They were then washed in 0.09 M KH2PO4 buffer with 7.5% sucrose and transferred to a 1% OsO4 plus 1.5% ferrocyanide solution buffered with veronal at pH 7.4 for subsequent immersion fixation for 1 h at 4°C. After washing in veronal buffer with 7% sucrose at pH 7.4, dehydration was carried out rapidly in graded ethanol series. Samples were then incubated overnight in propylene oxide and Epon (1:1), and subsequently embedded in Epon. Serial 80-nm sections were stained with uranyl acetate, lead citrate, and coded. We used a Philips CM100 electron microscope to count plasma cells and examine their ultrastructure in five representative sections for each sample.

**Statistical analysis**

GraphPad Prism 4 was used for statistical analyses. We compared normally distributed values using one- or two-way ANOVA analyses, as well as Bonferroni post hoc tests. A two-sided *p* value ≤ 0.05 was considered significant. Values are expressed as means ± SEM unless stated otherwise. We used Spearman (nonparametric) correlation coefficients (ρ).

**Results**

**Culturing EOMG thymic cells**

The donor patients are listed in Table 1. Their thymic plasma cells were identified by their characteristic ultrastructural morphology (Fig. 1), intense internal IgG staining, and surface CD138 expression (Fig. 2A), although the latter was a dim and not totally consistent marker (as previously noted for cryostored cells) (37). They were frequently found in clumps of three to five cells (or sometimes more), in close contact with extracellular matrix and other cell types (Fig. 2A), as in their survival niches in the spleen or bone marrow (38).

In the thymus, there is normally a high rate of cell death in vivo (32, 33), primarily due to the programmed death of immature thymocytes deprived of prosurvival signals. As expected, it was also substantial in our suspension cultures of frozen/thawed cells; even from hyperplastic EOMG thymi, most cells are immature thymocytes (7, 35) and are no longer in contact with the rare epithelial cells on which their survival normally depends. About 20% of the input cells remained viable on day 14, and fewer in irradiated samples (∼8%).

Patients MG-1 through MG-9 were thymectomized in London and their thymic cell suspensions were stored in liquid nitrogen at the Neuroscience Group Biobank (Oxford University); MG-10 was thymectomized in Maastricht (the Netherlands) and cells were tested fresh. None of the patients received immunosuppressive drugs before thymectomy, and all thymi showed follicular hyperplasia.

**FIGURE 1.** Ultrastructural changes in plasma cells incubated with bortezomib. (A) Normal plasma cells in control samples. Note the typical morphology, with elaborate ER and eccentric nuclei (with a cartwheel heterochromatin configuration). (B) Most plasma cells also appeared largely normal after 2 h of treatment with 2.5 μM bortezomib. (C) After 8 h of treatment with bortezomib, most plasma cells appeared apoptotic, with heterochromatin condensed around the perimeter of the nucleus and distension of the ER lumen. After 24 h with bortezomib, no plasma cells could be detected. Coded cell samples were postfixed with osmium tetroxide and counterstained with uranyl acetate and lead citrate. Images are representative of the conditions analyzed. Scale bars, 2 μm.

Absolute values for all the parameters measured in these cultures are shown in Table II. To maximize plasma cell recovery/activity, we used cells that had been dispersed with dispase and collagenase and then cryostored (7, 35); these cells behaved very similarly to fresh thymic cells in culture, with their AChR Ab and total IgG productivity often slightly exceeding that of their fresh counterparts, probably reflecting plasma cell enrichment by depletion of thymocytes (35). In fact, cells cultured from one fresh EOMG thymus gave substantially similar results (see below; Supplemental Fig. 1, Table II). Autoantibody production also appeared highly dependent on cell concentration and on adherent “feeder” fibroblasts and macrophages (35). Although microenvironments are probably not optimal in vitro, spontaneous autoantibody and total IgG production was nonetheless relatively consistent in quadruplicate wells from most of the thymi tested (Fig. 2D, 2F). Remarkably, both persisted for at least 2 wk, even after irradiation (Fig. 3), although only occasional viable macrophages and fibroblasts could still be seen (not shown), again highlighting that small numbers of plasma cells are able to produce substantial amounts of IgG/autoantibody (Table II).

**Bortezomib rapidly induces apoptosis in plasma cells from EOMG thymi**

We precultured thawed EOMG thymic cells for 3 d before adding 2.5 μM bortezomib. This concentration was based on previous in vitro experiments on human plasma cells (39) and the peak concentration measured in MM patients (40).

In all control samples, plasma cell ultrastructure appeared normal, with elaborate endoplasmic reticulum (ER), a well-defined...
Golgi complex, and dense regions of (nuclear) heterochromatin in the characteristic “cartwheel” distribution (Fig. 1A). They still appeared largely normal at 2 and 4 h after addition of bortezomib (at 2.5 μM; Fig. 1B). However, after 8 h, most surviving plasma cells showed signs of apoptosis (Fig. 1C), including dense condensations of chromatin around most of the nuclear membrane.
Bortezomib eliminates plasma cells in cultured EOMG thymic cells

To focus on long-lived plasma cells, we next added bortezomib, lenalidomide, or dexamethasone on days 7 and 11 of culture and counted surviving plasma cells on day 14. Lenalidomide was used at 10 μM, based on previous in vitro studies (42–44) and peak levels in MM patients (45). Dexamethasone was tested at 10 nM, a level known to inhibit lymphocyte proliferation in susceptible humans (46, 47).

We used thymic cells from six patients to test effects of these drugs on plasma cell numbers. Three days after a second dose of bortezomib, plasma cells were almost undetectable in all cases (p < 0.001; Fig. 2B, Supplemental Fig. 2). Interestingly, their numbers were not changed greatly or consistently by either lenalidomide or dexamethasone (p < 0.05 for the latter). In a separate experiment, we confirmed that 10 μM lenalidomide suppressed IgG production by PWM-stimulated PBMCs (not shown), as previously reported (29).

Proteasome inhibition halts spontaneous secretion of total IgG and AChR autoantibodies

In thymic cell cultures that were analyzed at early time points, we could already detect significant production of both AChR Ab and total IgG at 48 h of culture; both increased further from days 9 to 14 in the control and lenalidomide cultures (Fig. 2C, 2E). In striking contrast, they both consistently declined sharply after the first dose of bortezomib, and further still after the second dose (p < 0.001). Notably, dexamethasone merely prevented their rise after day 9, which correlated with the mild reduction in plasma cell survival observed by day 14. Results were broadly similar with the one fresh thymus available to us (Supplemental Fig. 1, Table II). At day 14, production of AChR Ab and total IgG was strongly and significantly reduced by bortezomib compared with both other conditions in all tested patients (Fig. 2D, 2F).

Cell suspensions from five thymi were irradiated and cultured for 2 wk. Plasma cells were detected in all of these cultures, although at lower frequencies than in their nonirradiated counterparts from the same patients (Table II). There was also very substantial, persisting production of total IgG in all cases (Fig. 3C). After irradiation, AChR Ab production remained strong in one patient (Fig. 3B) and above background in a second (Table II). Interestingly, when numbers of surviving plasma cells were sufficient (in patients MG-1, MG-5, and MG-6), they were reduced only by bortezomib (p < 0.001; Fig. 3A). Notably, both autoantibody and total IgG production were completely unaffected by dexamethasone, but both were again inhibited >90% by bortezomib (p < 0.001; Fig. 3B, 3C). When all results were combined, numbers of plasma cells (whether irradiated or not) correlated strongly with spontaneous secretion of total IgG and AChR Abs (p = 0.84/p < 0.0001 and p = 0.66/p < 0.0001, respectively).

To test for effects on other cell types, we next stained unirradiated cultured cells for CD3 and CD19. Both dexamethasone (at 10 nM) and bortezomib (at 2.5 μM) reduced the numbers of T and B cells after the first dose (day 7; p < 0.001 and p < 0.05, respectively), and to a similar extent (Fig. 4C, 4E), although dexamethasone had much less effect than bortezomib on Ab levels. In contrast, lenalidomide (at 10 μM) had no significant effect on either cell numbers or AChR Ab/total IgG production (Fig. 4B, 4D, 4F). Taken together with the strong correlation between total IgG production and plasma cell survival, these results deeply implicate plasma cells, rather than B cells, in the spontaneous Ab production that we observed in vitro.

Dose dependence of bortezomib and dexamethasone effects on plasma cell numbers and function

We next tested broader concentration ranges of dexamethasone and bortezomib in cultures from one fresh and six cryopreserved EOMG thymi. Total IgG and autoantibody productivity and plasma cell numbers were all minimal in the presence of 10 nM–10 μM bortezomib (Fig. 5, Supplemental Fig. 2D); leukemia and MM cell lines also have IC50 of 10–20 nM (48). In sharp contrast, dexamethasone had no significant effects, even at 1 μM. Thus, the minimum dose of bortezomib for eliminating plasma cells in vitro is apparently 10 nM. We also tested broader concentrations of lenalidomide, but did not observe any significant effects on plasma cell survival or function (not shown).

To assess their general toxicity, we sampled cultures at earlier times after addition of these drugs. At 6, 24, and 48 h, we found no significant differences in overall viability (Supplemental Fig. 3). At day 7, viabilities were reduced more by dexamethasone at 1 μM than at 10 nM. The viabilities were still more reduced by bortezomib at 2.5 μM, but not significantly at 10 nM, where its effects were more selective for plasma cells.

Average values were used for normalization of data in Figs. 2–4. All measured values are from day 14 except for anti-AChR production; these values are from day 11. N/A, not analyzed.

Discussion

In this study we demonstrate that bortezomib selectively eliminates long-lived autoimmune plasma cells in cultured thymus cells from nine of nine EOMG patients analyzed. Their spontaneous AChR autoantibody and total IgG production were promptly and almost completely halted, even at 10 nM. At 0.25 and 2.5 μM (and within 8 h) it led to ultrastructural changes in plasma cells that are characteristic not only of ER stress but also of apoptosis, as seen in vivo as...
sequences, suggest that native AChR, which is continuously avail-
data, together with the Abs’ highly mutated H and L chain V region
stimulable production of AChR Abs in EOMG thymi (31). These
Fig. 4E, 4F), these evidently contributed minimally in untreated
was maintained despite depletion of B cells (by dexamethasone;
which correlated strongly with their survival. Moreover, because it
behavior in cells from EOMG bone marrow and spleen, it is clearly
not unique to the hyperplastic EOMG thymus; indeed, it was also
shown by thymic remnants from thymoma/MG patients (30, 31).
In previous studies, plasma cells from recently immunized mice
died after only 4 d in suspension cultures (49). In sharp contrast,
their Ig production was sustained in vitro for 2–4 wk in primary
cultures from human tonsils and GALT, and it was enhanced by
feeder cells and especially in whole organ cultures (50, 51). It
seems unlikely that equivalent survival niches were reconstituted
efficiently in our cultures of cryostored, and especially irradiated,
thymic cells. We suggest that the remarkable survival of the long-
lived plasma cells shown in the present study is due to their
coclustering (Fig. 2A) and/or to some degree of resilience or “self-
sufficiency.” Their radioresistance clearly shows that they are well
established in many EOMG thymi and scarcely replaced in cul-
Importantly, because bortezomib (but not dexamethasone)
reduced their numbers and Ab production to baseline in irradiated
samples, its targets must include long-lived plasma cells.
In sharp contrast with our results with bortezomib, but in
agreement with previous in vivo findings (22, 52), we found only
marginal effects of dexamethasone on plasma cell survival or
function, even when added twice at 1 μM, and only on unirradi-
cated cells. Evidently, most of the thymic plasma cells are dexam-
ethasone- as well as radioresistant; indeed, neither treatment
alone, or when combined, completely eliminated them in any of our
cultures. In theory, both treatments might also affect their sup-
porting cells and/or damage other short-lived plasma cells or plas-
mablasts. In vivo, however, their precursors may be steroid-insensitive
as well; we noted no obvious decrease in PWM-stimulated IgG re-
sponses by (radiosensitive) B cells from prednisone-pretreated patients;
rather, they appeared to be enriched (53).
The even smaller effects on plasma cells of the immunomod-
ulatory drug lenalidomide may seem surprising in view of its clear
benefits in MM patients (28, 29, 54). One possible explanation is
that its toxicity for MM cells is mainly related to the activation of
tumor suppressor genes and caspases that trigger apoptosis in
transformed cells (55–57), but probably not in their non-neoplastic
counterparts. Moreover, because lenalidomide also disrupts the
survival niches required by MM and plasma cells (58), its effects
may be underestimated in our cultures. Additionally, it is well
known for its disparate immunomodulatory properties, for exam-
ple, inhibiting Ig production by cultured PBMCs (29), but also
for augmenting Ab responses to vaccination (59) and enhancing
proliferation and activation of T cells (28, 58). Taken together, our
in vitro results indicate that, unlike MM cells, non-neoplastic
plasma cells are not directly killed by lenalidomide. However, its
possible effects on their niches in vivo might valuablecomple-
ment the direct actions of bortezomib in patients (42).
Both bortezomib (at higher concentrations) and dexamethasone
reduced CD19+ and CD3+ lymphocytes in our cultures. This is in line
with the reported effects of bortezomib on activated human B cells
(60) and total circulating B cells in experimental autoimmune MG
rats (26). Moreover, bortezomib influences T cell subset distributions,
inducing apoptosis in activated CD4+ T cells, preventing the acti-
vation of memory T cells (61), but preserving resting and regulatory
T cells (62–64), and promoting their de novo generation (64). Ad-
ditional effects of bortezomib on activated B and T cells, or on Ag-
presenting B cells, could be an advantage in treating MG patients, for
example, in preventing the generation of new autoreactive plasma
cells while also eliminating the existing long-lived subset.
The susceptibility of plasma cells that we observed in the present
study, even to 10 nM bortezomib, is striking. Treating autoimmune

**FIGURE 3.** Susceptibility of irradiated cells to experimental drugs.
Thymic cells were irradiated and subsequently cultured for 2 wk. Drugs
were added on days 7 and 11 (bortezomib at 2.5 μM, lenalidomide at 10 μM,
dexamethasone at 10 nM) and samples were collected and analyzed as
for Fig. 2. **A** Plasma cell survival from patients MG-1, MG-5, and MG-6
on day 14 shown as percentage of the absolute numbers in the control
cultures (Table II). **B** AChR autoantibody secretion from patient MG-1
on day 11. The AChR autoantibody production rate from patients MG-3,
MG-5, and MG-6 was below detection limit; in MG-2, it was just above
background. **C** IgG production rate from irradiated samples on day 14.
Each point represents one well (three per condition) from the indicated
patients; horizontal bars are median values. One-way ANOVA and Bon-
ferroni post hoc testing were used for statistical analyses.

well (26). As far as we know, these are the first demonstrations of
its efficacy directly on pathogenic autoantibody-producing human
plasma cells. Because bortezomib triggers apoptosis in non-neoplastic
plasma cells, even after a single dose, short low-dose regimens might
be sufficient to rapidly reduce their numbers and Ab levels in patients
with autoimmune disorders, thus “buying time” before standard im-
uosuppressive drugs take effect.

In our cultures, plasma cells seemed almost entirely responsible
for spontaneous production of both autoantibody and total IgG,
which correlated strongly with their survival. Moreover, because it
maintained despite depletion of B cells (by dexamethasone; Fig.
4E, 4F), these evidently contributed minimally in untreated
cultures (if at all). Indeed, we have rarely found signs of mitogen-
stimulable production of AChR Abs in EOMG thymi (31). These
data, together with the Abs’ highly mutated H and L chain V region
sequences, suggest that native AChR, which is continuously avail-
able in the thymus, is driving most Ab-producing cells to the ter-
ninal plasma cell stage (30). Because we have seen very similar
behavior in cells from EOMG bone marrow and spleen, it is clearly
not unique to the hyperplastic EOMG thymus; indeed, it was also
shown by thymic remnants from thymoma/MG patients (30, 31).

In previous studies, plasma cells from recently immunized mice
died after only 4 d in suspension cultures (49). In sharp contrast,
their Ig production was sustained in vitro for 2–4 wk in primary
cultures from human tonsils and GALT, and it was enhanced by
feeder cells and especially in whole organ cultures (50, 51). It
seems unlikely that equivalent survival niches were reconstituted
efficiently in our cultures of cryostored, and especially irradiated,
thymic cells. We suggest that the remarkable survival of the long-
lived plasma cells shown in the present study is due to their
coclustering (Fig. 2A) and/or to some degree of resilience or “self-
sufficiency.” Their radioresistance clearly shows that they are well
established in many EOMG thymi and scarcely replaced in cul-
Importantly, because bortezomib (but not dexamethasone)
reduced their numbers and Ab production to baseline in irradiated
samples, its targets must include long-lived plasma cells.
In sharp contrast with our results with bortezomib, but in
agreement with previous in vivo findings (22, 52), we found only
marginal effects of dexamethasone on plasma cell survival or
function, even when added twice at 1 μM, and only on unirradi-
cated cells. Evidently, most of the thymic plasma cells are dexam-
ethasone- as well as radioresistant; indeed, neither treatment
alone, or when combined, completely eliminated them in any of our
cultures. In theory, both treatments might also affect their sup-
porting cells and/or damage other short-lived plasma cells or plas-
mablasts. In vivo, however, their precursors may be steroid-insensitive
as well; we noted no obvious decrease in PWM-stimulated IgG re-
sponses by (radiosensitive) B cells from prednisone-pretreated patients;
rather, they appeared to be enriched (53).
The even smaller effects on plasma cells of the immunomod-
ulatory drug lenalidomide may seem surprising in view of its clear
benefits in MM patients (28, 29, 54). One possible explanation is
that its toxicity for MM cells is mainly related to the activation of
tumor suppressor genes and caspases that trigger apoptosis in
transformed cells (55–57), but probably not in their non-neoplastic
counterparts. Moreover, because lenalidomide also disrupts the
survival niches required by MM and plasma cells (58), its effects
may be underestimated in our cultures. Additionally, it is well
known for its disparate immunomodulatory properties, for exam-
ple, inhibiting Ig production by cultured PBMCs (29), but also
for augmenting Ab responses to vaccination (59) and enhancing
proliferation and activation of T cells (28, 58). Taken together, our
in vitro results indicate that, unlike MM cells, non-neoplastic
plasma cells are not directly killed by lenalidomide. However, its
possible effects on their niches in vivo might valuablecomple-
ment the direct actions of bortezomib in patients (42).
Both bortezomib (at higher concentrations) and dexamethasone
reduced CD19+ and CD3+ lymphocytes in our cultures. This is in line
with the reported effects of bortezomib on activated human B cells
(60) and total circulating B cells in experimental autoimmune MG
rats (26). Moreover, bortezomib influences T cell subset distributions,
inducing apoptosis in activated CD4+ T cells, preventing the acti-
vation of memory T cells (61), but preserving resting and regulatory
T cells (62–64), and promoting their de novo generation (64). Ad-
ditional effects of bortezomib on activated B and T cells, or on Ag-
presenting B cells, could be an advantage in treating MG patients, for
example, in preventing the generation of new autoreactive plasma
cells while also eliminating the existing long-lived subset.
The susceptibility of plasma cells that we observed in the present
study, even to 10 nM bortezomib, is striking. Treating autoimmune
patients with lower doses and shorter courses of bortezomib may offer valuable therapeutic benefits while minimizing side effects, because even partial elimination of pathogenic plasma cells might be adequate, especially when combined with plasma exchange (65, 66). At doses commonly used to treat MM, SLE, thrombotic thrombocytopenic purpura, and acute Ab-mediated transplant rejection (1.3 mg/m²; resulting in peak plasma levels of 600 nM) (40), bortezomib can cause serious thrombocytopenia or peripheral neuropathy, particularly in MM patients given other chemotherapeutics to eliminate as many neoplastic cells as possible. In contrast, adverse effects were significantly fewer with “light touch” regimens that maintained therapeutic effects in patients with hyperacute Ab-mediated transplant rejection (24, 65–67) and also in MM patients (40). Finally, some second generation proteasome inhibitors have equal or greater potency but lower neurotoxicity than bortezomib, and they are already being tested in clinical trials (68).

In conclusion, our study using EOMG thymic cells, in combination with our previous results in the experimental autoimmune MG model (26), gives proof-of-principle for using proteasome inhibitors for the elimination of non-neoplastic plasma cells in autoantibody-mediated disorders. This therapeutic strategy could have the important advantage of rapidly reducing autoantibody titers during the lag period before the standard immunosuppressants have taken full effect. However, this potential benefit needs to be balanced very carefully against the possibility that side effects still persist at very low doses of bortezomib.

Acknowledgments
We are very grateful to Dr. Henry. Kaminski and Dr. Marguerite E. Hill for helpful discussions, to the patients for their samples, and to E. Goodger and the late Prof. John Newsom-Davis for access to them. We are also very grateful to Dr. Jan Damoiseaux and Jozien Jaspers-Spits for granting access to their

FIGURE 4. Quantitative overview of the drug effects on B and T lymphocytes. Thymic cells were cultured for 2 wk and drugs were added on days 7 and 11 (indicated by arrows). Cells were collected and labeled for FACS analysis on days 0, 2, 9, and 14. Samples were gated to exclude cell debris and selected for viable (PI−) cells and for either CD3 or CD19. In (A), (C), and (E), each point represents the average of samples from patients MG-1, MG-2, and MG-3 (three per patient). Error bars correspond to the SEM. Each point in panels (B), (D), and (F) represents one well (three per condition) from the indicated patients for day 14; horizontal bars are median values. Results are normalized as for Fig. 2B, and absolute cell numbers shown in Table II. One-way ANOVA and Bonferroni post hoc testing were used for statistical analyses.
FIGURE 5. Dose-response curves for plasma cell numbers (A), AChR Ab production (B), and total IgG secretion (C) after addition of drugs on day 4 and assay on day 7. Thymic cells from patients MG-1 and MG-3 were used in (A), cells from MG-4 and MG-5 in (B), and cells from MG-1, MG-3, MG-4, MG-5, MG-7, and MG-8 were used in (C). Each point represents the average of the normalized results for all the patients analyzed (at least three replicates per patient) and error bars represent the SEM. One-way ANOVA and Bonferroni post hoc testing were used for statistical analyses. ***p < 0.001 compared with the untreated cultures (open square).

EFFECT OF BORTEZOMIB ON MG PLASMA CELLS
