Macroautophagy Regulates Energy Metabolism during Effector T Cell Activation

Vanessa M. Hubbard,* Rut Valdor,* Bindi Patel,†,* Rajat Singh,†,* Ana Maria Cuervo,†,* and Fernando Macian*†

Macroautophagy is a highly conserved mechanism of lysosomal-mediated protein degradation that plays a key role in maintaining cellular homeostasis by recycling amino acids, reducing the amount of damaged proteins, and regulating protein levels in response to extracellular signals. We have found that macroautophagy is induced after effector T cell activation. Engagement of the TCR and CD28 results in enhanced microtubule-associated protein 1 light chain 3 (LC3) processing, increased numbers of LC3-containing vesicles, and increased LC3 flux, indicating active autophagosome formation and clearance. The autophagosomes formed in stimulated T cells actively fuse with lysosomes to degrade their cargo. Using a conditional KO mouse model where Atg7, a critical gene for macroautophagy, is specifically deleted in T cells, we have found that macroautophagy-deficient effector Th cells have defective IL-2 and IFN-γ production and reduced proliferation after stimulation, with no significant increase in apoptosis. We have found that ATP generation is decreased when autophagy is blocked, and defects in activation-induced cytokine production are restored when an exogenous energy source is added to macroautophagy-deficient T cells. Furthermore, we present evidence showing that the nature of the cargo inside autophagic vesicles found in resting T cells differs from the cargo of autophagosomes in activated T cells, where mitochondria and other organelles are selectively excluded. These results suggest that macroautophagy is an actively regulated process in T cells that can be induced in response to TCR engagement to accommodate the bioenergetic requirements of activated T cells. The Journal of Immunology, 2010, 185: 000–000.

Protein turnover is necessary not only to reduce the accumulation of damaged proteins in the cell and to recycle amino acids for new protein synthesis but also to allow for the modification of protein levels in response to extracellular signals (1–4). A major pathway involved in the degradation of long-lived proteins is macroautophagy, a catabolic process that delivers cytoplasmic material to lysosomes. Degradation of proteins by autophagy plays a key role in maintenance of correct cell homeostasis, which requires a careful balance between protein synthesis and protein degradation (5).

Macroautophagy is a form of autophagy responsible for the degradation of cytosolic proteins and whole organelles. This process is critical to maintain cell function, as its failure leads to intracellular accumulation of damaged proteins, defective regulation of many cellular processes, and altered responses to stress, which appear to underlie the basis for different human diseases (4, 6). Macroautophagy involves sequestering of cargo into a de novo-formed double-membrane vesicle called the autophagosome (7). Eventually, the autophagosomes fuse with lysosomes, and breakdown of the cargo occurs. Two ubiquitin-like conjugation systems regulated by autophagy-related gene (Atg)7 are involved in the biogenesis of the autophagosome: Atg8 (LC3)-phosphatidyl ethanolamine and Atg12-Atg5 (8, 9). Macroautophagy is regulated by the PI3K class III Vps34, which forms a complex with Beclin1 and stimulates autophagosome nucleation (7). Knocking down the proteins involved in the conjugation processes (e.g., Atg5 or Atg7) or inhibiting PI3K class III causes inhibition of macroautophagy.

Although the role of macroautophagy in several tissues and systems has been characterized, it is still unclear what role this process may play in the regulation of the adaptive immune system. Presentation of intracellular Ags on MHC class II molecules by dendritic cells has been shown to be mediated by macroautophagy, which is also active in thymic epithelial cells, where it plays a key role in the regulation of thymocyte selection and therefore in shaping the T cell repertoire (10). Macroautophagy also regulates B cell survival and development (11).

It is only recently that a possible role for macroautophagy in the regulation of T cell homeostasis has been proposed. Indeed, macroautophagy has been shown to control apoptosis and proliferation of peripheral T cells and also to regulate growth-factor withdrawal–induced cell death in CD4+ T cells (12, 13). Macroautophagy is also activated in CD4+ T cells when the CXCR4 receptor is engaged by the HIV-1 Env protein, which leads to cell death (14). Recently, macroautophagy has been proposed to be a major regulatory process of mitochondrial turnover during T cell development (15). However, the functional role of macroautophagy during T cell activation is still not fully understood.

After Ag recognition, T cells need to go rapidly from a resting to an activated state to respond to that Ag and proliferate. T cell...
activation imposes a vast bioenergetics challenge to sustain a rapid transition, which involves the activation of a new transcriptional program (16). This process results in a change in the cell proteome that is needed for activation and survival. Macroautophagy has been shown in other systems to play a critical role in maintaining amino acid and energy homeostasis (3, 17). In this study, we show that macroautophagy is upregulated upon activation in CD4⁺ T cells. Furthermore, using macroautophagy-deficient T cells, we show that macroautophagy activation is required to maintain cell proliferation and cytokine production. Finally, we describe what we believe is a novel role for macroautophagy during T cell activation in which selective cargo sequestration allows this catabolic process to regulate energy metabolism during T cell activation.

Materials and Methods

Mice

Six to eight-week-old C57BL/6 mice were purchased from The Jackson Laboratory (Bar Harbor, ME) and were maintained in pathogen-free conditions. To generate mice with a T cell-specific KO of macroautophagy, Atg7f/f mice (provided by M. Komatsu and K. Tanaka, Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan) were crossed with mice T cells were stimulated with 0.5 µg/ml plate-bound anti-CD3 and anti-CD28 in 96-well plates. Sixty hours later, BrdU was added for 12 h. Incorporation of BrdU was measured by ELISA according to the manufacturer’s instructions (Roche).

Measurement of ATP levels

ATP levels were assessed using a bioluminescence assay kit (Roche, Indianapolis, IN) following the manufacturer’s instructions.

Lactate measurements

Th1 cells were cultured with plate-bound anti-CD3 and anti-CD28 in the presence or absence of inhibitors of lysosomal activity. Lactate release into the media was determined at different time points using a lactate assay kit (MBL, Woburn, MA) following the manufacturer’s recommendations.

Measurement of TG utilization

T cells were cultured with 14C-oleate–BSA complex for 4 h. Cells were then extensively washed and stimulated with plate-bound anti-CD3 and anti-CD28 in the presence or absence of NH4Cl and leupeptin. At different time points, cellular lipids were extracted with hexane/isopropanol (3:2), dried, and redissolved in chloroform. Samples were resolved by TLC. Phosphorimager images were obtained and quantified with a Storm Imaging System (GE Healthcare, Waukesha, WI).

Measurement of intracellular protein degradation

Activated T cells were incubated with [3H]leucine (2 µCi/ml) for 48 h at 37°C and then extensively washed and maintained during the chase in medium containing an excess of unlabeled leucine (2.8 µM) to prevent reutilization of the radioabeled leucine. Aliquots of the medium taken at different times, run on an SDS gel, and analyzed by autoradiography.

Measurement of ATP levels

ATP levels were assessed using a bioluminescence assay kit (Roche, Indianapolis, IN) following the manufacturer’s instructions.

MD) in 15–20 different micrographs for each condition after thresholding. Autophagic vacuoles were identified by visual inspection of the micrographs using previously established criteria (8, 21, 22). Briefly, autophagic vacuoles (vesicles <0.5 μm) were classified as autophagosomes when they met two or more of the following criteria: double membranes (complete or at least partially visible), absence of ribosomes attached to the cytosolic side of the membrane, luminal density similar to cytosol, and identifiable organelles or regions of organelles in their lumens. Vesicles of similar size but with a single membrane (or less than 40% of the membrane visible as double), luminal density lower than the surrounding cytosol, and multiple single membrane-limited vesicles containing light or dense amorphous material were classified as autophagolysosomes. For morphometric purposes, both types of autophagic vesicles were pooled together in this study as we did not find differences in the maturation of these compartments between resting and stimulated cells.

Statistical analysis

Differences between multiple groups were analyzed by ANOVA with a Tukey posttest. Comparisons between specific pairs of groups were analyzed with a t test.

Results

Macroautophagy is induced during activation in effector Th cells

Macroautophagy has been shown to be active in naive T cells and to regulate T cell homeostasis and survival (12, 23). In many cell types, macroautophagy is activated in response to different cellular stresses. To determine if macroautophagy could also be regulated in a similar manner in T cells, we measured macroautophagy activity after T cell activation in effector Th cells. In vitro-differentiated primary mouse Th1 cells were activated with plate-bound anti-CD3 and anti-CD28 for 6 h, and autophagosome formation was assessed by immunofluorescence using Abs against LC3, a commonly used marker for autophagic vacuoles (8). Analysis of the stimulated effector Th cells revealed that although there was a basal level of macroautophagic activity in T cells, macroautophagy was activated in response to TCR and costimulation engagement. The number of vesicles that stained for LC3 was significantly higher in activated T cells (Fig. 1A, 1B). These results were corroborated by measuring the conversion of LC3-I into its PE-conjugated form, LC3-II, which also showed a significant increase in activated T cells (Fig. 1C, 1D). To determine if active degradation of autophagosomes occurred in these conditions, formation of LC3+ vacuoles and LC3 conjugation were also monitored in the presence of inhibitors of lysosomal proteolysis (NH4Cl and leupeptin), as comparison with untreated cells allows measuring autophagic flow (19). Cells that were stimulated in the presence of the inhibitors of lysosomal degradation showed significantly higher numbers of LC3+ vacuoles (Fig. 1A, 1B) and LC3-II (Fig. 1C, 1D) compared with that of cells that were activated in the absence of inhibitors, supporting enhanced active degradation of autophagosome cargo in activated T cells. Furthermore, detection of LAMP-1 in many LC3+ vacuoles indicated formation of autophagolysosomes (autophagosome/lysosome fusion) in activated T cells.

Activation of CD4+ T cells has been shown to require the engagement of two different signals: one provided by recognition of MHC class II–peptide complexes (signal 1) by the TCR, and a second signal that results from costimulatory receptors, such as CD28. In the absence of signal 2, T cells do not activate properly and enter into an anergic state, which renders them unresponsive to subsequent Ag encounters (24, 25). Signals through the IL-2R can also lead to full activation and prevent the establishment of clonal anergy in cells activated in the absence of costimulation (26). Active degradation of autophagosome cargo should result in increased proteolysis in activated T cells. Therefore, to determine whether costimulation would enhance autophagic activity, we performed pulse and chase experiments to measure proteolysis of long half-life proteins. Levels of total protein degradation were compared in cells activated with anti-CD3, anti-CD3 and anti-CD28, or anti-CD3 and IL-2. Most of the proteolysis detected in

Macrophagy is induced during activation in effector Th cells. A, Murine CD4+ cells were polarized to Th1 cells for 6 d and then stimulated with plate-bound anti-CD3 and anti-CD28 in the presence or absence of 20 mM NH4Cl and 100 μM Leup. Immunofluorescence analysis was performed using Abs against LC3 and LAMP-1. Secondary Abs coupled with FITC or Texas Red were used to detect the anti-LC3 and anti–LAMP-1 Abs, respectively. Cell nuclei were stained with DAPI. Original magnification ×100. Arrowheads indicate the presence of LC3+ autophagic vacuoles. B, Quantification of the number of LC3 puncta per cell in Rest and Stim cells from three independent experiments (mean ± SEM). *p < 0.05; **p < 0.01. C and D, Lysates from resting or plate-bound anti-CD3 and anti-CD28 stimulated T cells in the presence or absence of NH4Cl and Leup were immunoblotted with Abs against LC3. The blot is representative of three experiments that were quantified using ImageJ software. Results of the quantification of the levels of LC3-II relative to actin are shown in D as mean ± SEM. *p < 0.05. All experiments shown in A–D were performed 4–6 h after stimulation. E, Th1 cells were labeled with [3H]leucine for 48 h. Cells were then left resting or stimulated with either plate-bound anti-CD3, anti-CD3 plus anti-CD28, or plate-bound anti-CD3 plus anti-CD28 plus IL-2 (10 U/ml) and chased in medium containing an excess of unlabeled leucine for 24 h. Analysis of proteolysis rates (left) and levels of proteolysis after 24 h of stimulation (right) with or without costimulation are shown. Results are mean ± SEM of calculated total levels of proteolysis from five to seven different experiments. *p < 0.05. Leup, leupeptin; Rest, resting; Stim, stimulated.
these assays was mediated by lysosomal activity, as close to 80% inhibition was achieved using NH₄Cl (Supplemental Fig. 1). These experiments showed that signals provided by CD28 or IL-2R engagement induced a significant increase of the proteolytic activity in effector T cells (Fig. 1E). These results confirmed that the enhanced autophagosome formation and macroautophagy activation observed in stimulated Th cells resulted in increased degradation of cargo through the autophagic pathway.

**Blockade of macroautophagy inhibits T cell activation**

Our previous results showed that stimulated T cells activated macroautophagy. To clarify the role of macroautophagy in the regulation of T cell activity, we determined the effect of blocking macroautophagy in activation-induced cytokine production and proliferation. Leupeptin and NH₄Cl were used to block lysosomal proteolysis and 3-methyladenine to inhibit autophagosome formation. Inhibition of autophagy resulted in a dramatic decrease in IL-2 and IFN-γ production and profoundly impaired T cell proliferation (Fig. 2) in the absence of any increase in cell death (Supplemental Fig. 2).

To avoid possible off-target effects of using these inhibitors and to determine whether decreased cytokine production and proliferation were in fact attributable to macroautophagy blockade, we generated mice genetically deficient in macroautophagy in T cells (Atg7F/F-Lck-Cre). As previously reported, total number of thymocytes and peripheral T cells were reduced in these mice. However, differences between control and Atg7-deficient mice were reduced as animals aged, suggesting the possibility of a compensatory mechanism being activated. For this reason, we only used 3- to 6-wk-old mice for our analysis (Supplemental Fig. 3 and data not shown). Naive CD4+ T cells defective in the macroautophagy machinery also showed decreased IL-2 and IFN-γ production (Fig. 3A and B). CD4+ T cells from Atg7F/F-Cre-ER mice or control littermates were polarized to Th1 cells and then treated with 2 mM 4-hydroxytamoxifen for 48 h prior to stimulation with plate-bound anti-CD3 and anti-CD28 Abs. IL-2 production was determined by ELISA. Data are shown as mean + SEM of three independent experiments. *p < 0.05; **p < 0.01.

**FIGURE 2.** Inhibition of macroautophagy inhibits T cell activation. Mouse Th1 cells were stimulated with plate-bound anti-CD3 and anti-CD28 in the presence or absence of 10 mM 3-methyladenine (3-MA) or 20 mM NH₄Cl and 100 μM leupeptin and (A) IL-2 production, (B) IFN-γ production, and (C) cell proliferation (BrdU incorporation) measured after 24 h. Results are mean + SEM from three to four different experiments. *p < 0.05, **p < 0.01.

**FIGURE 3.** Genetic blockade of macroautophagy inhibits T cell activation. A and B, Naive CD4+ T cells from Atg7F/F-Lck-Cre mice or control mice were stimulated with plate-bound anti-CD3 and anti-CD28 Abs. IL-2 production was determined by ELISA (A), and proliferation was measured by BrdU incorporation (B). Results show the mean + SEM of three independent experiments. *p < 0.05; **p < 0.01. C, CD4+ T cells from Atg7F/F-Cre-ER mice or control littermates were polarized to Th1 cells and then treated with 2 mM 4-hydroxytamoxifen for 48 h prior to stimulation with plate-bound anti-CD3 and anti-CD28 Abs. IL-2 production was determined by ELISA. Data are shown as mean + SEM of three independent experiments. *p < 0.05.
duction and defective activation-induced cell proliferation in response stimulation (Fig. 3A, 3B). Annexin V staining confirmed that this effect was not due to higher levels of activation-induced cell death, as we could not detect any significant increase in cell death in activated macroautophagy-deficient T cells (Supplemental Fig. 2). Low levels of activation-induced proliferation prevented us from differentiating polarized populations of Th1 cells in vitro. For that purpose, we isolated CD4+ T cells from Atg7fl/fl-Cre-ER mice and differentiated them in vitro into Th1 cells. Deletion of the floxed Atg7 allele was achieved using 4-hydroxytamoxifen (control T cells were also treated with this drug). As previously seen in our experiments using autophagy inhibitors, blocking autophagy through deletion of Atg7 resulted in decreased activation-induced cytokine production (Fig. 3C). This effect was not due to defective secretion, as real-time PCR analysis revealed markedly decreased Il2 mRNA production in macroautophagy-deficient Th1 cells (Supplemental Fig. 4). Furthermore, the inhibition of T cell responses when autophagy was blocked did not appear to be caused by increased downregulation of the TCR, as levels of TCR surface expression were not reduced in Atg7-deficient T cells (Supplemental Fig. 5A). Similarly, CD28 signaling did not seem to be affected, and T cell activation-induced AKT phosphorylation was maintained in cells where lysosomal proteolysis had been inhibited (Supplemental Fig. 5B). Because macroautophagy has been implicated in the control of levels of oxidized proteins in cells, and reactive oxygen species (ROS) are readily produced after T cell activation, we also determined if macroautophagy control of ROS could be playing a role during T cell activation. We performed experiments in autophagy competent or inhibited Th1 cells that were stimulated in the presence or absence of the antioxidant N-acetylcysteine. We found that addition of antioxidants did not rescue the defect seen in IL-2 production in autophagy-compromised cells (Supplemental Fig. 5C). In fact, N-acetylcysteine appeared to decrease IL-2 production in our control cells, indicating that ROS production may be needed for T cell activation (27).

Macroautophagy activation is required to ensure sufficient energy production during T cell activation

T cell activation is a highly metabolic and dynamic process that requires a large amount of energy (16). The fact that blockade of macroautophagy was enough to inhibit T cell proliferation in activated cells supports that activation of macroautophagy under these conditions is not merely required to isolate particular cytosolic components through autophagosome sequestration, but that breakdown of cargo—and likely reutilization of its constituents—is necessary. In fact, macroautophagy is not only involved in the renovation of the cell proteome and organelle homeostasis but can also regulate the generation of energy through the use of the amino acids produced from the degradation of proteins in the lysosomes (3, 17). To test this hypothesis, we measured how ATP production might be affected by the inhibition of autophagy. T cells obtain ATP as a result of breakdown of glucose, amino acids, and lipids during oxidative phosphorylation. During T cell activation, there is a metabolic switch to ensure sufficient energy to promote proliferation and effector functions. This energetically demanding process leads to activation of glycolysis as a result of ligation of CD28 and upregulation of the expression of the glucose transporter 1 with subsequent increase in glucose uptake. However, T cells can still conserve their function under glucose-restrictive conditions indicating that other mechanisms may also cooperate with glycolysis and contribute to support the increase in ATP consumption that occurs during T cell activation (28). Macroautophagy has been shown to play a critical role in energy homeostasis. To clarify the role of autophagy in the regulation of energy homeostasis in T cells, we measured ATP production in cells where autophagy had been inhibited. We found that the increase in ATP production induced by TCR plus CD28 engagement was inhibited when autophagy was blocked (Fig. 4A and Supplemental Fig. 6A). This defective production of ATP correlated with a decrease in the production of lactate and in fatty acid use and AMPK phosphorylation in cells treated with lysosomal inhibitors (Supplemental Figs. 6 and 7). Autophagy has recently been shown to contribute to mobilization of intracellular lipid stores (29), and, consequently, the lack of fatty acid use could also be in part due to the reduced lipolysis observed in cells with compromised autophagy. It is interesting to note that we also found that phosphorylation of the ribosomal protein S6 kinase S6K1, a mammalian target of rapamycin (mTOR) substrate, was downregulated in these cells, suggesting the possibility that a decreased capability to recycle essential intracellular macromolecules through degradation might have induced inhibition of mTOR activity (Supplemental Fig. 7). Supplementation of our cultures with methyl pyruvate, a cell-permeable intermediate of glucose metabolism that has been shown to maintain the viability of...
upregulated in peripheral CD4⁺ T cells in response to the engagement of the TCR and costimulatory receptors. In activated T cells, exclusion of mitochondria and other organelles from autophagic vacuoles leads to the degradation of cargo different to the one present in basal autophagosomes. Furthermore, induction of macroautophagy is essential to support T cell activation. When macroautophagy is blocked, activated T cells show profound defects in their proliferative responses and their ability to secrete cytokines. This effect is, at least in part, due to the defects in energy metabolism caused by macroautophagy blockade.

Recently, macroautophagy has been reported to regulate growth-factor withdrawal–induced cell death in a Th2 cell line, as autophagy-deficient D10 cells became more resistant to apoptosis induced by culture in media without growth factors (12). Autophagy has also been suggested to control cell death induced by IFN-γ signaling in Th cells (31). Our results show that induction of macroautophagy during effector Th1 cell activation does not initiate or control activation-induced cell death, as levels of apoptosis in macroautophagy-deficient T cells after stimulation were similar to those found in control cells. It has recently been shown that in activated CD8⁺ T cells, the extent of macroautophagy activation is controlled by the interaction of a complex formed by the Fas-associated death domain protein and caspase 8 with Atg5, Atg12, and Atg16L1, which prevents the induction of receptor TNFR superfamily-interacting serine/threonine kinase 1-dependent necrosis (32). This fine regulation of macroautophagy in activated T cells would allow for a regulatory effect of macroautophagy in T cell activation independent of its possible ability to induce cell death in other conditions (12).

Whereas basal autophagy may likely contribute to T cell homeostasis and protein and organelle renewal (13), our results indicate that macroautophagy is activated in stimulated cells, where this proteolytic process plays a role different from basal cell homeostasis or death regulation. Pharmacological or genetic blockade of macroautophagy has been reported to preferentially affect activation-induced proliferation in CD8⁺ T cells (23). Our data reveal that macroautophagy also regulates proliferative responses on Th cells. Furthermore, our results show that Th cells activated in the presence of the inhibitors of lysosomal proteolysis NH₄Cl and leupeptin, as well as Atg7-deficient T cells, also have a profound defect in their ability to produce effector cytokines. This impairment is due to deficient transcription and not to possible interference with cytokine secretion.

Macroulaphagy has been shown to be important for the degradation of existing proteins to provide amino acids for synthesis of new proteins to guarantee survival during stress conditions. Activation of T cells is a highly demanding bioenergetic process. T cells require increased production of energy to sustain growth, proliferation, and the de novo synthesis of effector molecules (16, 33). Increased glycolysis has been shown to play a central role in supporting this new demand of energy (34). Signals transmitted by engagement of CD28 and transduced through the activation of AKT lead not only to the upregulation of the expression for the glucose transporter 1 and subsequent increase in glucose uptake but also to an increase in glucose metabolism (35). However, to some extent, T cells still conserve their function even in environments with very low glucose, suggesting that other mechanisms may cooperate with glycolysis and contribute to support the increased bioenergetic consumption that occurs in T cells after activation (28). For instance, activation of β-oxidation by AMPK1 has been shown to overcome the dependence on glycolysis of some cell types (36). Our results show that at least one of the key functions that macroautophagy fulfills in T cells is to guarantee an adequate energy metabolism in activated effector Th cells. This role of macroautophagy has previously been characterized in several cell types in response to starvation conditions, in which breakdown of nonessential cellular components
provides a source of energy and macromolecule building blocks to ensure cell survival (30). Our results indicate that this function of macroautophagy is not limited to ensure survival during cell starvation but that it is also necessary in other processes that require a high demand of energy, such as T cell activation. Notably, the inability of anergic T cells to respond to restimulation has been shown to correlate with a failure to induce the mechanisms required to increase their metabolic activity (37). Furthermore, T cell activation in the presence of metabolic inhibition mimics activation in the absence of costimulation and renders the T cell anergic (37). Our results show that costimulation is required to induce autophagy-mediated increase in proteolysis in activated T cells, as anergizing stimulation with anti-CD3 in the absence of CD28 engagement fails to do so. This defect can also be reversed through signaling by the

FIGURE 5. Ultrastructural analysis of the autophagic compartments in resting and stimulated T cells. Resting T cells and cells stimulated for 4 h with plate-bound anti-CD3 and anti-CD28 were processed for electron microscopy analysis. A, Lower-magnification fields (original magnification ×12,000) to show representative cells. Black arrows, autophagic vacuoles with distinguishable content; white arrows, autophagic vacuoles with electrolucent content or content of comparable density to the surrounding cytosol. B, Higher-magnification fields (original magnification ×20,000) to show individual autophagic vacuoles and their content. Scale bars, 1 μm. C–F, Morphometric analysis was performed in 15–20 micrographs (original magnification ×12,000), corresponding to cells from two different experiments. The number of AVs per field (C), vacuole average size (D), percentage of cellular area occupied by autophagic vacuoles (E), and percentage of vacuoles with soluble or particulate cargo (F) are shown. Values are mean ± SEM. Differences between resting and stimulated cells: **p < 0.01; ***p < 0.001. AVs, autophagic vacuoles.
IL-2R, which is also able to reverse the anergic phenotype (24–26, 38). Regulation of macroautophagy may therefore control the metabolic activity of T cells and contribute to determine the fate of T cells to be activated and proliferate or to become anergic. The molecular mechanisms that may induce macroautophagy in activated T cells are still not clear. Recent work has implicated Jun kinases, which in T cells are fully activated in the presence of co-stimulatory signals, in the activation of macroautophagy (39–42). JNK1 can phosphorylate Bcl-2 favoring its dissociation from Beclin1, which is then able to activate autophagy (41). The expression of Beclin1 has also been reported to be upregulated in activated Jurkat cells by direct p65-mediated transcription (43). In any case, it is interesting to note that costimulation in T cells leads to the activation of the AKT/mTOR pathway, which has been extensively characterized as an inhibitor of macroautophagy activation by inhibiting the mammalian Atg13 complex (44, 45). Therefore, it is likely that macroautophagy in T cells may be activated through an mTOR-independent mechanism. mTOR-independent activation of macroautophagy has recently been characterized in several systems in response to accumulation of cytosolic protein aggregates, and it is regulated by calcium/calpain or cAMP/fosnitol trisphosphate signaling (46–48).

Basal macroautophagy in T cells has recently been shown to play an important role in T cell development by regulating the turnover of mitochondria (15, 49). Our results corroborate this observation, as we have seen that the cargo of basal autophagosomes in resting T cells is composed mostly of cellular organelles with a high representation of mitochondria. However, in activated T cells, the cargo that is found inside autophagic vacuoles is qualitatively different. Our data show that most of the autophagosomes found in stimulated cells had a content of similar density as the cytosol, suggesting a selective degradation of soluble cytosolic components. The presence of mitochondria in those autophagosomes was drastically reduced compared with that of resting cells. The need for increased ATP production and the important role of the mitochondria in the regulation of calcium signaling (50, 51) could explain why these organelles are spared from turnover during activation, and macroautophagy turns to the degradation of cytosolic soluble components to ensure a sufficient energetic and metabolic output. Although initially thought to be a regulated but nondiscriminative process, evidence has mounted in the past several years indicating that macroautophagy can also be a selective process (52). Degradation of mitochondria by mitophagy and selective degradation of highly ubiquitinated protein aggregates are two examples of this ability of macroautophagy to select cargo (53–56). In fact, several cargo-recognition molecules also able to interact with components of the autophagic machinery, such as p62 or NBR1, have recently been identified (57, 58). How this selectivity is established in activated T cells remains to be characterized. In this case, “selective exclusion” rather than selective recognition seems to take place. Previous studies have shown that changes in mitochondria fusion–fission properties determine their susceptibility for autophagic degradation (59). Although further studies are required, the fact that the average size of mitochondria in stimulated cells was larger than in resting cells may offer a mechanism to preserve these organelles from degradation during T cell stimulation. However, changes during T cell activation in the properties of the surface markers of highly functional mitochondria, in the intracellular location of these mitochondria, in the site of formation of autophagosomes, or in the cytoskeleton network that contributes to bring these two compartments together could also be behind the avoidance of mitochondria from macroautophagy degradation. In addition to amino acids, it is possible that macroautophagy degradation of cytoplasmic soluble regions may also contribute free fatty acids and glycogen as additional sources of energy, as breakdown of both lipid stores and glycogen deposits by macroautophagy has been described (29, 60).

We present evidence of a novel role for macroautophagy during T cell activation. Regulation of the energy needs of activated T cells is favored by the ability of autophagosomes to exclude from their cargo mitochondria, which are required for signal transduction and activation in response to TCR engagement. It still remains to be determined if macroautophagy may regulate other T cell function during activation and if situations that result in vivo in compromised autophagy, such as aging or certain metabolic disorders, may also cause limited ability to recycle intracellular macromolecules that may lead to defective T cell responses.
