Microbial Infection-Induced Expansion of Effector T Cells Overcomes the Suppressive Effects of Regulatory T Cells via an IL-2 Deprivation Mechanism

Alicia Benson, Sean Murray, Prashanthi Divakar, Nikolay Burnaevskiy, Reed Pifer, James Forman, and Felix Yarovinsky

Regulatory Foxp3+ T cells are a critical cell population that suppresses T cell activation in response to microbial and viral pathogens. We identify a cell-intrinsic mechanism by which effector CD4+ T cells overcome the suppressive effects of regulatory T (Treg) cells in the context of three distinct infections: Toxoplasma gondii, Listeria monocytogenes, and vaccinia virus. The acute responses to the parasitic, bacterial, and viral pathogens resulted in a transient reduction in frequency and absolute number of Treg cells. The infection-induced partial loss of Treg cells was essential for the initiation of potent Th1 responses and host protection against the pathogens. The observed disappearance of Treg cells was a result of insufficiency in IL-2 caused by the expansion of pathogen-specific CD4+ T cells with a limited capacity of IL-2 production. Exogenous IL-2 treatment during the parasitic, bacterial, and viral infections completely prevented the loss of Treg cells, but restoration of Treg cells resulted in a greatly enhanced susceptibility to the pathogens. These results demonstrate that the transient reduction in Treg cells induced by pathogens via IL-2 deprivation is essential for optimal T cell responses and host resistance to microbial and viral pathogens. The Journal of Immunology, 2012, 188: 000–000.

Foxp3+ regulatory T (Treg) cells exert pleiotropic immunoregulatory effects essential for immune homeostasis, the prevention of autoimmunity, and the regulation of pathogen-induced inflammatory reactions (1). The transcription factor Foxp3 controls Treg cell development and function, and deficiency in the Foxp3 gene results in hyperactivation of CD4+ T cells, overproduction of proinflammatory cytokines, and massive multiorgan pathology (2, 3). It was initially thought that the functions of Treg cells were limited to the control of immune responses to autoantigens, but later studies demonstrated that Treg cells also exert suppressive effects on the immune responses to tumors (4) and infectious Ags (5, 6). These and other studies formally established that Treg cells have profound effects on immunity toward pathogens (7). A number of distinct suppressive mechanisms by which Treg cells target APCs, in particular dendritic cells (DC), and T lymphocytes have been identified (8). The dominant suppressor functions of Treg cells present a serious obstacle in the establishment of robust protective immunity toward pathogens; several studies with bacterial, viral, or parasitic infections formally demonstrated that Treg cells restrict the efficiency and magnitude of T cell responses, which results in an increased pathogen burden (9–11). Some studies have also revealed that by limiting immune responses to an infectious agent, Treg cells minimize tissue damage and potentiate a rapid pathogen clearance (12, 13). Importantly, the potential reciprocal interactions between effector and Treg cells during the initiation of immune responses are not completely understood.

In this report, we establish a CD4+ T cell-intrinsic mechanism for overcoming the suppressive effects of Treg cells upon the induction of protective T cell responses in the context of three distinct infections: Toxoplasma gondii, Listeria monocytogenes, and vaccinia virus. We observed that the acute responses to the investigated infectious agents resulted in the dramatic loss of Treg cells. This infection-induced reduction of Treg cells was essential for the initiation of potent Th1 responses and host protection against the parasitic, bacterial, and viral infections. Furthermore, we identified a mechanism responsible for the transient disappearance of Treg cells. We observed that the pathogen-induced expansion of effector T cells was associated with a limited amount of available IL-2. The lack of this growth factor, which is known to be essential for Treg cell development and survival (14), resulted in the loss of Treg cells during the acute response to the pathogens. The infection-induced Treg cell deficiency was completely prevented by treatment with exogenous IL-2 during the course of the experimental diseases. However, the restoration of Treg cells by IL-2 treatment had a negative impact on the induction of Th1 responses and resulted in greatly enhanced susceptibility to the microbial and viral pathogens. Taken together, our results establish that the pathogen-induced transient reduction in Treg numbers caused by IL-2 insufficiency is essential for optimal effector CD4+ T cell responses and host resistance to the parasitic, bacterial, and viral pathogens. Furthermore, because the observed loss of Treg cells was transient and incomplete, it enhanced the protective immune responses to pathogens, but it did not result in severe immunopathology. Our results also suggest that thymus-derived Treg cells, rather than those that develop through peripheral conversion, have a major role in Treg reconstitution following the acute response to microbial pathogens.
Materials and Methods

Animals

C57BL/6 mice were obtained from the University of Texas Southwest-
ern (UTSW) Medical Center Mouse Breeding Core Facility. B6.Cg-
Foxp3tm2Tch/J (Foxp3EGFP) mice were obtained from The Jackson Lab-
oratory. All animals used were age- and sex-matched and maintained in the
specific pathogen-free barrier facility at the UTSW Medical Center at Dallas.
All experiments were performed using protocols approved by the
Institutional Animal Care and Use Committees of the UTSW Medical Center.

Parasitic, bacterial, and viral infections

Mice were infected i.p. or orally with an average of 20 T. gondii (ME49
strain) cysts as previously described (15). For infection of mice with L.
monocytogenes, log-phase cultures of L. monocytogenes (10403 srsotype)
were washed twice and diluted in PBS to the desired concentration. L.
monocytogenes was injected in the lateral tail vein at 10^5 CFU per mouse.
Vaccinia virus was injected in the lateral tail vein at a dosage of 10^6 PFU
per mouse.

IL-2 treatment

rIL-2 and the anti-mouse IL-2 mAb (clone JES6-1A12) were purchased from eBioscience. The IL-2/anti-IL-2 complex was prepared as described
previously (16) with a few minor modifications: 50 µg anti-IL-2 Ab was
mixed with 1.5 µg rIL-2 in 200 µl PBS 15 min prior to i.p. injection on
days 3 and 5 postinfection with T. gondii, L. monocytogenes, or vaccinia
virus.

Flow cytometry and ELISA

On days 3, 5, 7, 10, 14, and 15 postinfection, the animals were necropsied,
and their spleens and mesenteric lymph nodes were harvested for the
analysis of Treg cells by flow cytometry. Cells were stained in ice-cold
FACS buffer, stained with PerCP-Cy5.5–labeled anti-CD4 mAb or anti-
CD8 mAb, and fixed for 40 min in BD Cytofix/Cytoperm (BD Biosciences).
Cells were then stained using fluorochrome-conjugated Abs
according to the manufacturer’s protocol (BD Biosciences). In short, after
incubation in the permeabilization buffer supplemented with anti-FcγRII/
III mAb (2.4G2; 5 µg/ml) at 4°C, cells were stained for 30 min with FITC-
labeled anti-TNF, PE-labeled anti-IL-2, and allophycocyanin-labeled anti-
IFN-γ mAb (BD Biosciences), washed three times, and resuspended in
PBS plus 1% FBS. Cell fluorescence was measured using an FACS-Calibur
or LSR II flow cytometer (BD Biosciences), and data were analyzed using
FlowJo software (Tree Star, Ashland, OR).

Flow cytometric analysis of CD4+Foxp3+ Treg cells was performed using the
mouse/rat Foxp3 Staining Set (eBioscience) as recommended by the
manufacturer.

The aldehyde dehydrogenase (ALDH)-positive cells were detected using an
ALDEFLUOR staining kit (StemCell Technologies). Splenocytes from
naive and infected mice were incubated in the dark for 35 min at 37°C in
the ALDEFLUOR assay buffer containing the activated ALDEFLUOR
substrate (StemCell Technologies), with or without the ALDH inhibitor
diethylaminobenzaldehyde. Cells were subsequently stained using the
CD11b-, CD11c-, and Gr-1-specific Abs (BD Biosciences) and analyzed on
an LSR II flow cytometer (BD Biosciences). Naive GFP–Foxp3–CD4+ T
t cells were sort-purified from the spleen of the Foxp3EGFP (B6.Cg-
Foxp3tm2Tch/J) mice. Sort-purified GFP–Foxp3–CD4+ T cells (10^5
cells/well) were cocultured with ALDH+CD11b+CD11c– or CD11c+ cells
(2 × 10^5 cells/well) in the presence of an anti-CD3 mAb (0.5 µg/ml; BD
Biosciences). In some experiments, ALDH+CD11b+CD11c– and CD11c+
cells were mixed together with the GFP–CD4+ T cells. TGF-β (3 ng/ml)
and IL-2 (5 ng/ml) were purchased from eBioscience. After 3 d of culture,
Foxp3 expression was measured by flow cytometry. The data were ana-
alyzed using FlowJo software (Tree Star).

IL-2 and IFN-γ in culture supernatants were measured by ELISA using
commercially available kits (R&D Systems for IFN-γ and eBioscience for
IL-2).

Reverse-transcription PCR

RNA was isolated from splenocytes; sort or magnetic beads (Miltenyi
Biotec) purified CD4+, CD8+, CD4+Foxp3EGFP cells with The PureLink
RNA Mini Kit (Invitrogen). cDNA was prepared using the SuperScript III
kit (Invitrogen). Optimized primers targeting each gene (Foxp3: 5'-
CATGCTACGTTCCTCCAC-3', 5'-CTGGACCCATTCGACAGT-3';
TGF-β: 5'-ATGCGAAGTCCGATCGGCT-3', 5'-GGAGCTCTGGATTGCA
CTC-3'; ifng: 5'-ACTGCGAAAAGAAGATGGATGAC-3'; 5'-TGAAGCTTCT
GAATGTCTTG-3'; cd25: 5'-AGAACACACGGATTCTG-3'; 5'-AGC
TGCGCCTACTGCTACCTTA-3'; and hprt 5'-GGCTTGAATAAGAGAT
TACTCAGG-3', 5'-TCAACTTTCGCTCATCTTGAAG-3') were designed
using the Primer 3 software. cDNA was amplified with Power SYBR Green
master mix (Applied Biosystems). The MyQ Real-Time PCR Detection
System (Bio-Rad) was used to obtain cycle threshold values. The relative
expression of each sample was determined after normalization to hypo-
xanthine phosphoribosyltransferase using the ddCt method.

Statistical analysis

All data were analyzed with Prism (version 5; GraphPad). Data were
considered statistically significant for p values <0.05 using a two-tailed t
test.

Results

Acute responses to parasitic, bacterial, and viral infections
result in the transient loss of Treg cells

Treg cells are involved in the potent regulation of the immune
response to a variety of microbial pathogens. For this reason, we
investigated the interactions between the induction of the protective
T cells and that of regulatory Foxp3+CD4+ T cells in the context of
infection with three distinct pathogens: the parasite T. gondii, the
Gram-positive bacteria L. monocytogenes, and vaccinia virus.

T. gondii is a protozoan parasite that stimulates potent and rapid
Th1-biased CD4+ T cell immune responses (17). A protective
immune response to this pathogen requires a delicate balance
between proinflammatory effector mechanisms, primarily regu-
lated by the TLR-dependent activation of MyD88, and concomi-
tant induction of an anti-inflammatory program (17, 18). Lack
of either of these mechanisms results in high susceptibility to this
parasite, as is evident from the rapid mortality observed in T.
gondii-infected MyD88–/– and IL-10–/– mice (19–21). Because
Treg cells have an important role in the limitation of T cell
responses, we investigated the reciprocal interactions between
IFN-γ/CD4+ T cells and regulatory Foxp3+CD4+ T cells during
the acute response to T. gondii. We observed that systemic
infection with the parasite resulted in a dramatic reduction in the
frequency of Foxp3+CD4+ T cells by days 5–7 postinfection (Fig.
1A, 1D). As is evident from Fig. 1A and 1D, the observed loss of
Treg cells during T. gondii infection was transient, and Treg cells
recovered by the end of the acute response to the parasite.
In addition, the remaining Treg cells expressed reduced levels of
Foxp3 when compared with naïve controls (Fig. 1A).

The relative loss of Foxp3+CD4+ T cells in the T. gondii-
infected mice was also observed during the analysis of Foxp3
mRNA expression in splenocytes and isolated CD4+ T cells (Fig.
1B). We observed a substantial reduction in the amount of Foxp3
mRNA seen in splenocytes and purified CD4+ T cells isolated
from T. gondii–infected mice when compared with their
naïve controls (Fig. 1B). In addition, a reduction of Foxp3 mRNA levels
in the Treg cells themselves was observed in the T. gondii–infected
mice (Fig. 1B). The latter observation was consistent with the flow
cytometry data demonstrating that infection with the parasite
resulted not only in the loss of Treg cells, but also in reduced
levels of Foxp3 seen in the infected mice (Fig. 1A).

To examine the possibility that the observed loss of Treg cells
was an artifact of the experimental i.p. infection with the parasite,
we next used a natural (oral) route of T. gondii infection. Using
the oral route of infection, we observed a similar progressive
and transient partial depletion of Treg cells (Fig. 1C, 1D). Thus,
infection with the protozoan parasite resulted in the transient reduction in frequency of Treg cells during the acute response to the pathogen independently of the route of infection (Fig. 1A–D).

Because the Treg cell loss closely coincided with the peak of the CD4+ T cell response against *T. gondii*, the observed decrease in the frequency of CD4+Foxp3+ Treg cells measured by flow cytometric or Foxp3 signals detected by PCR approaches could be explained by the expansion of pathogen-specific effector CD4+ T cells. To address this possibility, we performed an absolute quantification of CD4+Foxp3+ and CD4+IFN-γ+ T cells during the course of the parasitic infection. The quantification of Treg cells in mice infected i.p. or orally with the parasite revealed that Treg cells (Fig. 1E) were almost undetectable at the peak of the CD4+ T cell response against *T. gondii* (Fig. 1F), formally demonstrating that *T. gondii* infection results in both absolute and relative loss of Treg cells. In addition, we also observed that the disappearance of Treg cells was not limited to the spleen but was also seen in all tissues examined (data not shown).

We next investigated whether the observed transient depletion of Treg cells is unique to the infection with the protozoan parasite *T. gondii* or whether it is a common feature of acute immune responses to microbial and viral pathogens. As a model bacterial pathogen, we selected *L. monocytogenes*, a Gram-positive bacterium that is responsible for severe disease in immunocompromised humans. Host resistance to this pathogen depends on an intact innate immune system and requires potent IFN-γ production by T cells (22). Similar to our observations postinfection with *T. gondii*, mice challenged with *L. monocytogenes* demonstrated a dramatic reduction of Treg cells, and this reduction had similar kinetics to those observed during the parasitic infection (Fig. 2A). Similar to the *T. gondii*-induced Treg cell loss, the depletion of Treg cells triggered by infection with *L. monocytogenes* was transient, and the Treg cell frequency returned to the levels typically seen in naive animals within 10–14 d postinfection (Fig. 2A).

Furthermore, we also observed that infection with vaccinia virus also resulted in the transient and systemic depletion of Treg cells (Fig. 2B). The kinetics of the Treg cell disappearance and recovery closely resembled those observed in *T. gondii- or L. monocytogenes*-infected mice (Figs. 1, 2). In all of the experimental infections (with the viral, bacterial, or parasitic pathogens), we observed that Treg cell depletion peaked by day 7 postinfection. Intriguingly, the loss of Treg cells was transient, and their fre-
frequency was largely restored within 2 wk of the infection (Figs. 1, 2).

Quantifications of Treg cells in *L. monocytogenes* - and vaccinia virus-infected mice formally established that both infections resulted in absolute reduction of Treg cells (Fig. 2C). Because both *L. monocytogenes* and vaccinia virus result in the expansion of effector CD4+ and CD8+ T cells (Fig. 2C), both infections caused a profound Treg cell insufficiency during the acute responses to these pathogens.

**Activation of TLRs not required for Treg cell disappearance**

It has been previously established that the innate recognition of pathogens by TLRs can overcome the suppressive effects of Treg cells. The activation of TLRs on APCs results in the production of soluble factors, including IL-6, which render effector CD4+ T cells resistant to the suppressive effects of Treg cells (23). TLR activation on Treg cells can result in the elimination of the immunosuppressive effects of this cell population (24–26). TLR activation in effector T cells modulates CD4+ and CD8+ T cell responses (27–29). During *T. gondii* infection, we previously established that TLR11 is a major innate immune sensor for the parasite that coordinates CD4+ T cell responses to the pathogen (18). We thus investigated whether TLR11 activation was required for the depletion of Treg cells during acute toxoplasmosis. We observed that similar to their wild-type (WT) counterparts, mice deficient in TLR11 demonstrated a progressive loss of Treg cells during both the systemic and mucosal responses to the parasite (Supplemental Fig. 1). The only differences between WT and TLR11-deficient mice were the slightly delayed kinetics and reduced magnitude of the disappearance of Treg cells in TLR11−/− mice. Furthermore, the analysis of *T. gondii*-infected TLR2-, TLR4-, TLR2 × TLR4-, and TLR9-deficient animals revealed that none of the examined TLRs were responsible for the loss of Treg cells during parasitic infection (data not shown). Taken together, our results suggest that TLR activation is dispensable for the infection-driven loss of Treg cells.

**Pathogen-specific CD4+ T cells produce limited amounts of IL-2**

We next determined the mechanism that was responsible for the disappearance of Treg cells during the course of parasitic, bacterial, and viral infections. We observed that the loss of Treg cells was independent of their proliferation status. During *T. gondii* infection, only a small fraction of Foxp3+ T cells was also positive for the proliferation marker Ki67 in infected WT mice, whereas Treg cells actively divided in mice infected with *L. monocytogenes* or vaccinia virus (Supplemental Fig. 2 and data not shown). Nevertheless, all three infections resulted in a similar loss of Foxp3+ T cells. We thus hypothesized that the infection-driven depletion of Treg cells was a result of a lack of a survival factor(s) essential for Treg cell maintenance.

Among various growth factors, IL-2 has an important role in the regulation of T cell function (30). Although IL-2 is essential for T cell proliferation in vitro, a central function for IL-2 in vivo is the regulation of T cell development and survival (14). The lack of IL-2 or of the components of the IL-2R results in a dramatic reduction in Treg cells in the thymus and in the periphery (14). We thus hypothesized that the infection-driven depletion of Treg cells was a result of a lack of a survival factor(s) essential for Treg cell maintenance. WT animals were infected with *T. gondii* using an i.p. or oral route, and intracellular staining for IFN-γ, TNF, and IL-2 was...
used to identify fully activated T. gondii-specific T cells. As previously reported (15, 17), T. gondii infection resulted in the rapid induction of CD4+ T cells producing high amounts of IFN-γ and TNF independently of the route of infection (Fig. 3A, Supplemental Fig. 3). In striking contrast, T. gondii-specific CD4+ T cells were largely deficient in the production of IL-2 (Fig. 3B, 3C, Supplemental Fig. 3A–C). Real-time PCR-based gene expression analysis also revealed a reverse correlation between expression of IL-2 and IFN-γ genes. We observed that T. gondii infections resulted not only in induction of IFN-γ (Fig. 3D), but also in the dramatic loss of IL-2 signals measured in purified T cells or bulk splenocytes isolated from infected mice (Fig. 3E). These observations were also confirmed by an ELISA assay that demonstrated a reduced amount of IL-2 detected in splenocytes from the infected mice (Fig. 3F, Supplemental Fig. 3D). Furthermore, T. gondii infection resulted in the upregulation of CD25, a high-affinity subunit of IL-2R, on the activated T cells (Fig. 3G).

The loss of IL-2 expression and acquisition of IFN-γ production resulted not only in induction of IFN-γ but also in the dramatic loss of IL-2 signals measured in purified T cells or bulk splenocytes isolated from infected mice (Fig. 3E). These observations were also confirmed by an ELISA assay that demonstrated a reduced amount of IL-2 detected in splenocytes from the infected mice (Fig. 3F, Supplemental Fig. 3D). Furthermore, T. gondii infection resulted in the upregulation of CD25, a high-affinity subunit of IL-2R, on the activated T cells (Fig. 3G, Supplemental Fig. 3E). These results suggest that the acquisition of IFN-γ secreting ability during T. gondii infection was associated with increased consumption of IL-2 coupled with reduced production of this cytokine.

Intracellular staining was next used to detect IFN-γ and IL-2 proteins during the course of L. monocytogenes and vaccinia virus infections. Similar to infection with the parasite, infection with the bacterial or viral pathogen also resulted in a high frequency of CD4+IFN-γ+ T cells (Fig. 4A, 4B). At the same time, only a small fraction of activated CD4+ T cells produced high levels of IL-2 (Fig. 4A, 4B). Real-time PCR (Fig. 4C) and ELISA (Fig. 4D) methods also confirmed the flow cytometric observation regarding the loss of IL-2 expression and acquisition of IFN-γ production during the acute responses to the pathogens.

Taken together, our results suggest that the effector phenotype during acute responses to T. gondii, L. monocytogenes, and vaccinia virus is associated with a limited ability to produce IL-2.

**Rescue of Treg cells by IL-2 negatively regulates the host resistance to microbial and viral infections**

We next investigated whether the limited production of IL-2, coupled with the expansion of pathogen-specific T cells, is responsible for the infection-induced loss of Treg cells. This hypothesis is based on previous experiments that revealed high sensitivity of Treg cells to the decreased availability of IL-2, as well as...
our observation regarding limited amounts of IL-2 produced by pathogen-specific CD4+ T cells (Figs. 3, 4). To directly examine this possibility, we determined whether exogenous treatment with IL-2 would prevent the disappearance of Treg cells caused by the microbial and viral infections.

Animals infected with T. gondii, L. monocytogenes, or vaccinia virus were additionally treated with an IL-2/anti–IL-2 complex, which is known to increase the biological activity of the cytokine (16). As is evident in Fig. 5, IL-2 supplementation during the course of all of these infections prevented the disappearance of Treg cells. IL-2 treatment completely prevented the loss of Treg cells triggered by T. gondii infection (irrespective of the route of infection) in the spleen (Fig. 5A–C) and in all of the examined tissues (data not shown). Similarly, IL-2 treatment of L. monocytogenes- or vaccinia virus-infected mice prevented the loss of Treg cells (Fig. 5D–F). These results suggested that insufficiency of IL-2 is a major cause of the loss of Treg cells triggered by the parasitic, bacterial, and viral pathogens.

We next investigated the effects of Treg cell reconstitution on the induction of host resistance to T. gondii, L. monocytogenes, and vaccinia virus. We observed that IL-2 treatment of T. gondii-infected mice dramatically reduced the ability of CD4+ T cells to acquire a Th1 phenotype, a hallmark of the immune response to this parasite (Fig. 6A). Furthermore, the reconstitution of Treg cells resulted in increased mortality of the infected mice compared with WT animals without IL-2 treatment (Fig. 6B). These results strongly suggest that the infection-triggered depletion of Treg cells is essential for establishing a protective Th1 response during the acute response against the parasite. We also observed that in WT mice that survived the acute phase of toxoplasmosis, a short treatment with IL-2 at the initial phase of the adaptive immune response to the parasite that resulted in an enhanced brain cyst load during the chronic phase of the infection (Fig. 6B).

Similar to the results obtained with T. gondii-infected mice, we observed that in vivo IL-2 treatment impaired Th1 responses to L. monocytogenes and enhanced susceptibility to the pathogen (Fig. 6C). Whereas mock or untreated WT animals completely cleared L. monocytogenes by day 7 postinfection, animals that maintained the Treg cell population as a result of IL-2 treatment contained high numbers of bacteria (Fig. 6C). IL-2 treatment and Treg cell reconstitution in vaccinia virus-infected animals also had a major negative impact on the clearance of the virus (Fig. 6D).

Regeneration of Treg cells during microbial infection

Deficiency in IL-2 or Treg cells results in a fatal autoimmune disease affecting multiple organs (1, 14). In contrast, infection-induced loss of Treg cells was transient and even beneficial for the induction of pathogen-specific immune responses (Fig. 6). These observations suggest that mechanisms are in place that regulate Treg cell recovery following acute responses to pathogens. Because Treg cells can either originate from the thymus or develop as a result of peripheral conversion from naive T cells (1), we investigated the relative contribution of these mechanisms in the restoration of Treg cells.

The de novo induction of Treg cells in the periphery critically depends on the vitamin A metabolite retinoic acid, and cells expressing the ALDH enzymes are known to have a major role in the generation of inducible Treg cells (31). We used flow cytometry to analyze ALDH-expressing cells during the course of T. gondii infection. Whereas only a small number of cells expressed ALDH under steady-state conditions, we observed a rapid accumulation of ALDH+ cells in the spleen of infected animals during the acute response to the parasite (Fig. 7A, Supplemental Fig. 4). The ALDH-positive cells also expressed CD11b and Gr1, but not CD11c, surface markers (Supplemental Fig. 4 and data not shown). Intriguingly, the highest numbers of ALDH+ cells were detected in the T. gondii-infected mice at the start of Treg cell reconstitution (Fig. 7, Supplemental Fig. 4). To examine whether the infection-induced ALDH+ cells were responsible for the restoration of the Treg cell pool, we evaluated the capacity of CD11b+ALDH+ T cells to generate Treg cells in vitro from Foxp3-negative CD4+ T cells. Non-Treg naive CD4+ T cells were isolated from Foxp3-GFP mice and incubated with sorted ALDH+CD11b+CD11c− cells alone or with the addition of rIL-2 and TGF-β (Fig. 7B). For comparison, we also isolated CD11c+ DC from the same mice and analyzed the Treg cell conversion ability of these cells.
alone or in the combination with ALDH+ cells. We observed that ALDH+ cells alone or those cocultured with DC failed to induce Treg cells in the absence of TGF-β. The addition of this cytokine to the culture of DC (CD11c+MHC class II+ALDH2) or ALDH+CD11b+CD11c2 cells dramatically enhanced the ability of both cell populations to induce Treg cells (Fig. 7B). The addition of exogenous IL-2 resulted in a further increased generation of Treg cells. Nevertheless, under all tested conditions, ALDH+ cells were not superior to ALDH2 DC in the conversion of Foxp3-negative CD4+ T cells into Foxp3-positive lymphocytes (Fig. 7B). Furthermore, the efficient induction of Treg cells by ALDH+CD11b+ and CD11c+ cells was in part dependent on IL-2 (Fig. 7B), arguing against the possibility that the peripheral induction of Treg cells could compensate for the loss of Treg cells that results from infection-induced IL-2 insufficiency.

We next analyzed whether an increased production of Treg cells in the thymus could have a role in the reconstitution of Treg cells after the acute response to parasitic infection. We first observed that whereas the frequency of thymic Treg cells was reduced in T. gondii-infected mice (Fig. 8A, 8B), their loss was less prominent when compared with Treg cells in the periphery (Fig. 1). Intriguingly, at the peak of peripheral Treg cell loss (day 7, Fig. 1), we observed a relative expansion of thymic Foxp3+ cells that also expressed KI67, a marker of recently divided cells (Fig. 8A, 8C). Importantly, the thymic Treg cells rapidly recovered in both their absolute number and their frequency after the parasitic infection (Fig. 8B, 8D), suggesting that thymus-derived Treg cells, rather than the peripheral induction of Foxp3+CD4+ T cells, have a major role in Treg cell recovery following the acute response to the pathogen.

Discussion
Treg cells expressing the transcription factor Foxp3 contribute to the dominant control of self-reactive T cells, thus contributing to the maintenance of immunologic self-tolerance (1, 8). Solid evidence from experimental animals and clinical observations have demonstrated that the expansion and accumulation of these immunosuppressive cells correlates with advanced tumor growth and predicts poor prognosis during infectious diseases. Treg cells not only prevent the induction of tumor- or pathogen-specific CD4+ and CD8+ T cell responses but also limit the efficacy of vaccinations and other therapeutic interventions (1).

The effect of Treg cells in the context of host–pathogen interactions has been particularly extensively studied during chronic infectious diseases. In a model of cutaneous leishmaniasis, Treg cells are responsible for the suppression of effector T cells and the establishment of a persistent parasitic infection (5). The removal of Treg cells during malaria infection limited the expansion of the parasite and prevented the host from developing cerebral malaria (6, 9). The immunosuppressive effects of Treg cells are not limited to parasitic diseases. The depletion of Treg cells greatly enhanced antiviral responses during HIV and SIV infections (32–34). Similarly, failure to control hepatitis B and C viruses correlated with a high frequency of Treg cells (35). An important role for Treg cells in the progression of mycobacteria infection has also been demonstrated (10).
A role for Treg cells during the initiation of acute responses to pathogens is less clear. The profound inhibitory effects of Treg cells on the priming of pathogen- or model Ag-specific T cells have been well characterized (8). The experimental depletion of Treg cells resulted in greatly enhanced Th1 and Th2 responses and formally demonstrated a major role for Treg cells in the prevention of effector T cell activation (36, 37). What is not clear is how T cell responses are initiated in the presence of Treg cells in vivo. One mechanism of the modulation of the suppressive effects of Treg cells depends on the activation of TLRs on DC and other APCs (38). Because TLRs are involved in the recognition of all known groups of pathogens, including viruses, bacteria, fungi, and protozoa, TLR-dependent inhibition of the suppressive effects of Treg cells can coordinate the immune responses to all groups of microorganisms. More recent studies revealed that in addition to APC, murine and human Treg cells express high levels of several TLRs, but the effects of TLR activation on Treg cells remain controversial. For example, TLR5 activation by flagellin increases the suppressive activity of Treg cells (39). However, triggering of TLR8 on Treg cells results in the abrogation of their suppressive functions (24). The positive and negative effects of TLR2 activation on Treg cells depend on the nature of the TLR2 agonist (29). Similarly, TLR4 can both enhance and suppress Treg cell functions (40, 41). In this report, we identified a distinct self-regulated mechanism that allows effector T cells to avoid the suppressive effects of Treg cells. Importantly, this mechanism does not require TLR-mediated recognition of the pathogen but depends on the tight regulation of IL-2 availability.

We observed that the acute immune response to three distinct pathogens—*T. gondii*, *L. monocytogenes*, and vaccinia virus—resulted in the transient and systemic partial loss of Treg cells. The disappearance of Treg cells did not require TLR activation but rather correlated with the degree of effector T cell activation and the inability of the activated CD4+ T cells to produce IL-2. We observed that the rapid expansion of pathogen-specific Th1 CD4+ T cells resulted in a transient insufficiency of IL-2. Because IL-2 has a dominant role in Treg cell development and in the regulation of the suppressive functions of Treg cells (14), infection-induced insufficiency in IL-2 assures the loss of Treg cells during the initiation of pathogen-specific T cell responses. Our observations established that in contrary to the previous models in which deprivation of IL-2 was proposed to be a mechanism by which Treg cells could control effector T cells (42), limited amounts of IL-2 have more profound effects on Treg cells. Most importantly, we observed that the transient loss of Treg cells was essential for optimal host resistance to all of the tested pathogens: *T. gondii*, *L. monocytogenes*, and vaccinia virus. Prevention of the transient loss of Treg cells by treating the infected animals with IL-2...
resulted in impaired pathogen-specific responses and, in the case of parasitic infection, was responsible for the high mortality of the infected mice. Although Treg cell reconstitution did not result in mortality of vaccinia virus-infected mice, and only a small fraction of \textit{L. monocytogenes}-infected animals died after Treg cell reconstitution, a dramatic elevation of the pathogen loads was observed in all of the experimental infections. This enhanced susceptibility to viral and microbial infection correlated with impaired IFN-\(\gamma\) production by effector T cells.

A recent report from Belkaid and colleagues (13) revealed that the mucosal responses to \textit{T. gondii} are characterized by the disappearance of Treg cells, which causes lethal intestinal and liver pathology. Although we also observed that Treg cell reconstitution by IL-2 reduced the damage caused by the exaggerated immune responses to the parasite, several lines of evidence suggest that the main function for the transient loss of Treg cells is to enhance Th1 responses to pathogens. First, we established that \textit{T. gondii} is not a unique pathogen in its ability to cause the loss of Treg cells. Mice infected with \textit{L. monocytogenes} or vaccinia virus demonstrated a similar loss of Treg cells, but these bacterial and viral infections do not cause severe intestinal damage. Furthermore, we observed that systemic (i.p.) infection with \textit{T. gondii} also resulted in the IL-2–dependent disappearance of Treg cells, similar to that observed during the mucosal responses to the parasite. Because the intestinal pathology is triggered during mucosal, but not systemic, responses to the parasite, we conclude that although the infection-induced transient loss of Treg cells contributes to the pathological response, it is not sufficient for the initiation of the intestinal immunopathology. Indeed, we previously reported that TLR11-deficient animals are protected from \textit{T. gondii}-induced ileitis (15), but TLR11 activation was not required for the infection-induced loss of Treg cells. These results suggest that the observed transient loss of Treg cells caused by microbial infection has a distinct biological function. We propose that the loss of Treg cells caused by the limited ability of the pathogen-specific CD4\(^+\) T cells to produce IL-2 is an important regulatory mechanism that is essential for host resistance to microbial infections.

Ablation of Treg cells is not always beneficial for the acute response to pathogens. In the context of mucosal HSV infection, the ablation of Treg cells accelerates fatal infection associated with increased viral loads in the mucosa and CNS (12). This is because a complete lack of Treg cells results in uncoordinated responses to the virus, characterized by an exaggerated inflammatory reaction without the sufficient number of NK cells, DC, and T cells required for protection of the host against the HSV infection. Similarly, the complete depletion of Treg cells results in impaired respiratory syncytial virus clearance in the lung, which is associated with a delay in the recruitment of respiratory syncytial virus-specific CD8\(^+\) T cells (43). These studies clearly demonstrate that the complete and prolonged ablation of Treg cells can
be detrimental not only because of fatal autoimmune reactions, but also because of uncoordinated pathogen-specific immune responses. Our results revealed that *T. gondii*, *L. monocytogenes*, and vaccinia virus caused a transient and incomplete infection-induced Treg cell depletion. The rapid recovery of Treg cells correlated with the enhanced replication of thymic Foxp3^+^CD4^+^ T cells, suggesting that thymus-derived Treg cells have a major role in the restoration of Treg cells in the periphery. In addition, we observed that thymic Treg cells were more resistant to the infection-induced IL-2 deprivation, and our results are consistent with previous publications that established that in the absence of an IL-2 signal, the thymic production of Foxp3^+^CD4^+^ T cells was only partially reduced, indicating that thymic Treg cells are less sensitive to IL-2 deficiency (44, 45). In summary, we observed that parasitic, bacterial, and viral pathogens caused a prominent and transient loss of Treg cells. The infection-induced expansion of effector T cells was associated with a limited amount of IL-2 produced by activated CD4^+^ T cells, and the deficiency in this cytokine was responsible for the infection-triggered loss of Treg cells. Our results revealed that the naturally occurring partial depletion of Treg cells is essential for establishing protective immunity to *T. gondii*, *L. monocytogenes*, and vaccinia virus and suggest a mechanism that regulates adaptive immunity to pathogens that depends on the homeostatic IL-2-based interactions between regulatory IL-2^+^CD4^+^ CD T cells.

Supplemental Material

Supplemental Figure Legends

Figure S1. Frequency of Treg cells in T. gondii-infected TLR11-deficient mice.

TLR11-/- mice (five animals per group) were infected intraperitoneally (IP) or orally (ORAL) with an average of 20 T. gondii strain ME49 cysts per mouse, and the frequency of Treg cells was analyzed in the (A) spleen and (B) mesenteric lymph nodes at the indicated number of days post-infection. (C) Average frequency of Foxp3+ cells in the spleens and mLN of TLR11-/- mice infected intraperitoneally (blue circles) or orally (red circles). The data shown are representative of five independent experiments.

Figure S2. Analysis of Treg cell proliferation

(A) WT mice (five animals per group) were infected intraperitoneally (IP) with an average of 20 T. gondii strain ME49 cysts per mouse. Analysis of Treg cell proliferation was performed by intracellular staining for the nuclear antigen Ki-67 at the indicated number of days post-infection. The numbers were calculated as percentages of all CD4+ cells shown on the plots. The data shown are representative of four independent experiments. (B) WT mice (five animals per group) were infected intravenously with L. monocytogenes (10⁴ CFU per mouse) or (C) vaccinia virus (10⁶ PFU per mouse). Analysis of Treg cell proliferation was performed by intracellular staining for the nuclear antigen Ki-67 at the indicated number of days post-infection. The numbers were calculated as percentages of all CD4+ cells shown on the plots. The data shown are representative of four independent experiments.
Figure S3 *T. gondii*-specific Th1 CD4+ T cells produce limited amounts of IL-2

WT animals were (A) left untreated or were infected with *T. gondii* (B) intraperitoneally or (C) orally, and seven days later, the ability of CD4+ T cells isolated from the mesenteric lymph nodes to produce IFN-γ, TNF, and IL-2 was analyzed. The data shown are representative of four independent experiments. (D) WT animals were either left untreated (d0) or infected with *T. gondii* intraperitoneally and at the indicated time points post infection the ability of splenic CD4+ T cells to produce IL-2 and IFN-γ in response to *T. gondii* extract STAg (10 µg/ml) were analyzed. The data shown are representative of three independent experiments. (E) WT mice (five animals per group) were infected intraperitoneally with an average of 20 *T. gondii* strain ME49 cysts. CD25 expression was analyzed in splenic CD4+Foxp3- and CD4+Foxp3+ T cells isolated from naïve or *T. gondii* infected mice as shown in Figure 3G.

Figure S4. The appearance of ALDH+ cells in response to *T. gondii* infection.

Splenocytes from naïve and infected mice were incubated in the dark for 35 minutes at 37°C in the ALDEFLUOR assay buffer containing the activated ALDEFLUOR substrate, with or without the ALDH inhibitor diethylaminobenzaldehyde (DEAB). Cells were subsequently stained using the CD11b-, CD11c-, and Gr1-specific antibodies (BD Biosciences) and the appearance of ALDH+ cells in response to *T. gondii* infection was analyzed by flow cytometry on days 0, 7, 10, 14, 21, and 28 post-infection. The data shown are representative of three experiments.
