Inhibition of Epidermal Growth Factor Receptor Tyrosine Kinase Ameliorates Collagen-Induced Arthritis

Christina D. Swanson,*† Elliot H. Akama-Garren,* Emily A. Stein,*† Jacob D. Petralia,* Pedro J. Ruiz,* Abdolhossein Edalati,† Tamsin M. Lindstrom,*† and William H. Robinson*†

Rheumatoid arthritis (RA) is an autoimmune disease characterized by the formation of pannus and the destruction of cartilage and bone in the synovial joints. Although immune cells, which infiltrate the pannus and promote inflammation, play a prominent role in the pathogenesis of RA, other cell types also contribute. Proliferation of synovial fibroblasts, for example, underlies the formation of the pannus, while proliferation of endothelial cells results in neovascularization, which supports the growth of the pannus by supplying it with nutrients and oxygen. The synovial fibroblasts also promote inflammation in the synovium by producing cytokines and chemokines. Finally, osteoclasts cause the destruction of bone. In this study, we show that erlotinib, an inhibitor of the tyrosine kinase epidermal growth factor receptor (EGFR), reduces the severity of established collagen-induced arthritis, a mouse model of RA, and that it does so by targeting synovial fibroblasts, endothelial cells, and osteoclasts. Erlotinib-induced attenuation of autoimmune arthritis was associated with a reduction in number of osteoclasts and blood vessels, and erlotinib inhibited the formation of murine osteoclasts and the proliferation of human endothelial cells in vitro. Erlotinib also inhibited the proliferation and cytokine production of human synovial fibroblasts in vitro. Moreover, EGFR was highly expressed and activated in the synovium of mice with collagen-induced arthritis and patients with RA. Taken together, these findings suggest that EGFR plays a central role in the pathogenesis of RA and that EGFR inhibition may provide benefits in the treatment of RA. The Journal of Immunology, 2012, 188: 000–000.

Abbreviations used in this article: CIA, collagen-induced arthritis; CON-2, cyclooxygenase-2; EGF, epidermal growth factor; EGFR, EGF receptor; ERBB, erythroblastic leukemia viral oncogene homolog (ErbB)2 that naturally inhibits dimerization of ErbB receptors, effectively reduced the severity of collagen-induced arthritis (CIA), a mouse model of RA (6). Similarly, RB200, a ligand trap that inhibits responses from EGFR, ErbB2, and ErbB3, reduced CIA severity (7). These findings suggest that inhibiting EGFR may be beneficial in RA.

EGFR is a widely expressed member of the ErbB family of tyrosine kinase receptors (8) and is overexpressed in many tumors (8). Activation of EGFR promotes survival, proliferation, cytokine production, cell adhesion, blood vessel recruitment, and invasion depending on the cell type (8). Similar to a tumor, RA synovium is hyperplastic, invasive, and expresses EGFR. Specifically, EGFR is expressed on RA fibroblast cell lines and on the vascular endothelial cells and subsynovial fibroblasts of certain RA patients (9, 10). Moreover, levels of EGFR ligands, such as EGF, amphiregulin, or TGF-α, are significantly higher in synovial fluid, serum, or synovium of RA patients than in that of osteoarthritis patients or noninflammatory controls (9, 11, 12).

In this study, we elucidate the role of EGFR in RA. We show that levels of EGF ligands are abnormally high in the serum of RA patients and that EGFR is expressed and activated in RA synovial tissue. Moreover, we demonstrate that erlotinib hydrochloride (Tarceva), a small-molecule EGFR inhibitor that is Food and Drug
Administration approved for the treatment of metastatic non-small cell lung cancer (13), can attenuate CIA. Findings from our in situ and in vitro studies suggest that erlotinib ameliorates autoimmune arthritis by inhibiting the EGFR-dependent proliferation and cytokine production of synovial fibroblasts, proliferation of endothelial cells, and formation of osteoclasts.

Materials and Methods

**Serum and joint tissue samples**

Sera samples were collected from RA patients who met the 1987 American College of Rheumatology criteria and from healthy individuals under protocols approved by the Stanford University Institutional Review Board. Joint tissue was collected from RA patients undergoing knee arthroplasty and was snap-frozen in OCT freezing media.

**Reagents**

For animal studies, we used erlotinib tablets (OSI purchased from the Stanford Inpatient Pharmacy Service. Erlotinib tablets were formulated as a fine suspension with 0.5% (w/v) hydroxypropyl methylcellulose (Dow) and 0.1% (v/v) Tween 80 in distilled water. For in vitro studies, we used 99% pure, chemically synthesized erlotinib (LC Laboratories) stored as a 100 mM stock solution at −20°C in DMSO. PD153035 (Tocris Bioscience) was stored as a 10 mM stock solution at −20°C in DMSO. For all studies, we used recombinant murine EGF, murine platelet-derived growth factor β (PDGFβb), human EGF, human vascular endothelial growth factor (VEGF), murine M-CSF, and murine receptor activator for NF-κB ligand (RANKL) (PeproTech) reconstituted in water.

**Immunohistochemistry**

Seven-micrometer sections of synovial tissue from patients with RA were fixed in 4% (v/v) paraformaldehyde, permeabilized with Triton X-100, and probed with Abs against total EGFR (Rockland), p-EGFR (Y1068) (Abcam), von Willebrand factor (Millipore), or tartrate-resistant acid phosphatase (TRAP) (Abcam). Staining was developed using a Vectastain and stored as a 10 mM stock solution at 20°C in DMSO. PD153035 (Tocris Bioscience) was stored as a 10 mM stock solution at −20°C in DMSO. For all studies, we used recombinant murine EGF, murine platelet-derived growth factor β (PDGFβb), human EGF, human vascular endothelial growth factor (VEGF), murine M-CSF, and murine receptor activator for NF-κB ligand (RANKL) (PeproTech) reconstituted in water.

**CIA and K/BxN studies**

CIA was generated in 6- to 8-week-old male DBA/1 mice (The Jackson Laboratory) weighing ~20 g. Mice were used under protocols approved by the Administrative Panel on Laboratory Animal Care and in accordance with National Institutes of Health guidelines. For the induction of CIA, mice were first immunized with a s.c. tail injection of 100 μg bovine CII (Chondrex) emulsified in 100 μl CFA containing 250 μg/mouse heat-killed Mycobacterium tuberculosis H37Ra (BD Biosciences). Twenty-one days after the primary immunization, mice were boosted by s.c. injection at the base of the tail with 100 μg bovine CII emulsified in 100 μl IFA. Mice were assessed daily for signs of inflammatory arthritis. As each mouse reached a total paw score between 2 and 4, it was randomly assigned to a treatment group, based on arthritis severity assessed using both a visual scoring system and paw thickness measurements. For the visual scoring system, each mouse could have a maximal score of 16 because each limb was given a score of 0–4. Grade 0 indicated no swelling or erythema; grade 1, mild swelling and erythema; grade 2, moderate swelling and erythema; grade 3, pronounced swelling and erythema; and grade 4, severe swelling, erythema, and joint rigidity of the ankle, foot, and digits. Paw thickness was determined by measuring the thickness of the hind paws above the metatarsal region using 0- to 10-mm calipers. As each mouse reached a total paw score between 2 and 4, it was randomly assigned to a treatment group. Upon randomization into a treatment group, mice were given 0.2 ml vehicle, 10 mg/kg erlotinib, or 50 mg/kg erlotinib twice daily by oral gavage using a 1-ml syringe and a 20-gauge gavage needle (Fisher Scientific). All mouse groups were treated until inflammation in the vehicle-treated mice peaked and began to decrease, as assessed by visual score and paw thickness. At that time, feet and ankles were collected in formalin for histology.

K/BxN serum-transfer arthritis was induced in BALB/c mice by dual injections of 50 μl KRN serum diluted 1:1 in 1× PBS on day 0 and day 2. Mice were treated with either vehicle or 50 mg/kg erlotinib twice daily by oral gavage. Mice were scored as described above.

**Histopathology**

Mouse hind limbs were fixed in formalin, decalcified in Cal-Ex II (Fisher Scientific), and embedded in paraffin. Sections were stained with H&E and scored by an investigator blinded to the treatment group. Sections were evaluated for synovitis, pannus formation, and bone and/or cartilage destruction using a previously described scoring system: grade 0, normal; grade 1, mild inflammation, mild hyperplasia of the synovial lining layer, mild cartilage destruction without bone erosion; grades 2–4, increasing degrees of inflammatory cell infiltrates, synovial lining hyperplasia, and pannus formation and cartilage and bone destruction (14).

**Isolation and stimulation of synovial fibroblasts**

Synovial fibroblasts were isolated from remnant pannus obtained from RA patients during knee arthroplasty, as previously described (14), and cultured in RPMI 1640 containing 10% FCS, 2 mM l-glutamine, 100 U/ml penicillin, and 100 μg/ml streptomycin at 37°C. Cells were used for experiments between passages five and eight and exhibited typical characteristic fibroblast appearance. Moreover, cells were checked at passage six for purity and did not exhibit staining above background for CD3, CD14, CD20, and CD11c (Supplemental Fig. 1). For experiments, 1 × 10⁵ cells/cm² were plated in media containing 5% FBS, RPMI 1640, and penicillin/streptomycin and allowed to adhere for 24 h. Media were replenished, cells were pretreated with erlotinib or PD153035 for 30 min, and EGF or PDGFβb was added to cells for another 48 h. Supernatants were collected after 48 h for ELISA analysis.

**Endothelial cell stimulation**

HUVECs (Lonza) were cultured in endothelial growth media-2 (Lonza) on plates coated with 10 μg/cm² rat tail collagen I (Sigma-Aldrich). To evaluate HUVEC proliferation, we plated cells at a density of 1 × 10⁵ cells/cm² in complete media and allowed them to adhere overnight. Cells were then washed with 1× PBS and incubated with reduced-serum media containing endothelial basal media-2 (Lonza), 1% FBS, 2 mM l-glutamine, 100 U/ml penicillin, and 100 μg/ml streptomycin at 37°C, 5% CO₂ for 24 h. Cells were pretreated with erlotinib for 30 min, and EGF or VEGF was added for 72 h.

**Proliferation assays**

Brdu was used during the last 24 h incubation to evaluate synovial fibroblast and HUVEC proliferation. Brdu incorporation was assessed as a marker of proliferation by using a Brdu cell proliferation assay (Calbiochem) according to the manufacturer’s instructions.

**ELISAs**

Levels of EGF, betacellulin (PeproTech), amphiregulin, heparin-binding epidermal growth factor-like growth factor (HB-EGF), and TGF-α (R&D Systems) were determined by ELISA in serum samples diluted 1:2 to 1:200 in assay diluent. Levels of VEGF, IL-8, MCP-1 (PeproTech), and matrix metalloproteinase (MMP)-3 (R&D Systems) were determined by ELISA in supernatants collected from synovial fibroblast cultures 48 h after stimulation. For IgG ELISAs, plates were coated with 100 μg/ml bovine collagen II. Mouse serum diluted 25-fold was then added, followed by anti-IgG1-HRP or anti-IgG2a-HRP (SouthernBiotech) diluted 1:10,000 fold. Absorption was read at 450 nm.

**Osteoclast assays**

Bone marrow cells were isolated from naive, 7-week-old DBA/1J mice. Twenty-four hours after being isolated, undifferentiated (nonadherent) cells were collected and replated at 15 × 10⁶ cells/cm². Cells were stimulated with 40 ng/ml M-CSF (PeproTech) in complete α-MEM for 3 d. Differentiation medium containing 40 ng/ml M-CSF and 100 ng/ml RANKL (PeproTech) was then added for another 3–4 d, and osteoclast formation was monitored visually. For these studies, culture medium was refreshed every 2 d. Erlotinib or PD153035 was added to the cultures at the specified concentrations at the beginning of the differentiation period. For identification of TRAP⁺ cells, cells were washed with 1× PBS and stained using the acid phosphatase leukoocyte kit (Sigma-Aldrich). Eight photographs of each well at ×40 and ×100 were analyzed in a blinded manner. The number of osteoclasts per picture and the number of nuclei per osteoclast were counted. ImageJ was used to calculate the surface area of the...
osteclasts formed. For measurement of TRAP enzyme activity, cells were lysed at 4°C in a buffer containing 90 mM citrate, 0.1% Triton X-100, and 80 mM sodium taurocholate for 10 min. Substrate solution consisting of 20 mM p-nitrophenyl phosphate was then added to the wells for 1 h at room temperature. The reaction was stopped by the addition of 0.5 M NaOH, and plates were read at 405 nm. For bone resorption assays, osteoclasts were grown on dentine discs (Bolton) for 3 d with 40 ng/ml M-CSF and 6 d with 40 ng/ml M-CSF, 100 ng/ml RANKL, and erlotinib. Media was changed every two days. After 9 d, discs were washed with distilled water, gently rubbed with a cotton swab to remove attached cells, and stained with toluidine blue. Resorbed areas were photographed and analyzed using ImageJ software.

Quantification of mRNA expression

RNA isolation was performed using the RNeasy kit (Qiagen), and cDNA was made using the qScript cDNA synthesis kit (VWR). Real-time PCR was performed using PerfeCTa SYBR 2× mix (VWR). Primers, purchased from IDT, were as follows: human cycloxygenase-2 (COX-2), forward 5′-CCGGGGTACATCGACTTAT-3′, reverse 5′-GGGCTGTAAGCCGACAG-3′; human GAPDH, forward 5′-GAAGGTGTTGGCTCATTGTT-3′, reverse 5′-ATGGTTCACACCCATGACG-3′; murine Apc5, forward 5′-GCCAAACCTGATACCT-3′, reverse 5′-GCCAAACCTGATACCT-3′; murine Itgb3, forward 5′-CTTCCAATACGTGCAGCAGA-3′, reverse 5′-TCTTACCTACATTCC-3′; murine hypoxanthine phosphoribosyltransferase 1 (Hprt1), forward 5′-TGTTGTGGATAGTCCTGTGG-3′, reverse 5′-TGGACAACATCAACAGGCT-3′; murine Itgb3, forward 5′-CGCTC GGTGGTGGGT-3′, reverse 5′-ATTAGGAGTGGGATGCTG-3′, reverse 5′-ATCCAACCATACTCC-3′; murine Mmp3, forward 5′-TGTGACCTAAGGCGGACAG-3′, reverse 5′-AGCACCATAGAACCCAT-3′; murine Nfatc1, forward 5′-AATTAGGAGTGGGATGCTG-3′, reverse 5′-ATCCAACCATACTCC-3′; murine Pomp, forward 5′-GTGAGCGTTGTGTG-3′, reverse 5′-CTGTCGGCTGTG-3′; murine Pomp, forward 5′-CTGGTGGCTGTG-3′, reverse 5′-AGCACCATAGAACCCAT-3′; murine Ifnγ, forward 5′-CTGTCGGCTGTG-3′, reverse 5′-AGCACCATAGAACCCAT-3′; murine Pomp, forward 5′-GTGAGCGTTGTGTG-3′, reverse 5′-CTGTCGGCTGTG-3′.

Results

Levels of EGF are increased in RA serum

Which EGF ligands play a role in RA are unclear, with differing reports each suggesting that EGF, TGF-α, or amphiregulin is the important EGF ligand (9, 11, 12). We measured the concentration of the five best characterized EGF ligands in serum from RA patients and normal controls. Levels of EGF and betacellulin were significantly higher in sera from RA patients than in that from healthy individuals (Fig. 1A, Supplemental Fig. 2A). In contrast, serum levels of TGF-α, amphiregulin, or HB-EGF did not differ significantly between the two groups (Supplemental Fig. 2B–D). Thus, there is an increased capacity for activation of EGF signaling in patients with RA.

EGFR is expressed in RA and CIA joint tissue

We next examined whether the synovial tissue of patients with RA and of mice with CIA express EGF, and whether the EGFR in these tissues is activated. We found that RA synovial lining expresses high levels of both total EGF and tyrosine 1068-phosphorylated (Y1068) EGFR, the activated form of EGFR (Fig. 1B–D). Deeper within the RA synovial tissue, EGFR was expressed around high-endothelial venules and blood vessels (Fig. 1C). Likewise, EGFR and p-EGFR (Y1068) were highly expressed in areas of synovitis and around vessels in joint tissues of mice with CIA (Fig. 1E, 1F). Thus, EGFR is expressed and activated in synovial tissue in RA, as well as in the CIA model of RA.

EGFR inhibition reduces the severity of CIA

To investigate the role of EGFR in CIA, we administered 10 or 50 mg/kg erlotinib twice daily to mice with established CIA. These doses of erlotinib produce plasma concentrations in the same range as those achieved with human dosing (15, 16). Erlotinib treatment dose-dependently reduced the visual arthritis score and paw
thickness of mice with CIA (Fig. 2A, 2B). Histologically, it dose-dependently reduced the degree of pannus formation, synovitis, and cartilage and bone erosion in the paws of mice with CIA (Fig. 2C, 2D). This was not accompanied by a significant change in the IgG1 or IgG2a titers (Supplemental Fig. 3A, 3B). Similarly, erlotinib treatment also reduced the severity of disease in the K/BxN serum-transfer model (Supplemental Fig. 3C). Thus, erlotinib, at pharmacologically relevant doses, attenuates autoimmune arthritis in mice.

**Erlotinib reduces EGF-induced synovial fibroblast proliferation and cytokine production**

To elucidate erlotinib’s mechanism of action in treating autoimmune arthritis, we first examined its effects on synovial fibroblasts derived from RA patients. In RA, synovial fibroblasts become hyperplastic and invade the surrounding bone and cartilage, forming the pannus (17). EGFR ligands may increase the mitogenic capacity of synovial fibroblasts (9, 18–21), and erlotinib reduces EGF-induced synovial fibroblast proliferation and cytokine production through EGFR signaling pathways downstream of EGFR (8). These findings confirm that erlotinib suppresses proliferation and cytokine production by inhibiting EGFR signaling.

**Erlotinib reduces EGF-induced endothelial cell proliferation and COX-2 expression**

As we show in Fig. 1, endothelial cells in RA and CIA synovium express EGFR. Blood vessels, which are lined with endothelial cells, increase in number in RA synovium as compared with osteoarthritis or healthy synovium (26). Targeting the formation of these blood vessels in RA is hypothesized to have three beneficial consequences: it may reduce the growth of the synovium by decreasing the blood supply that provides nutrients, decrease the inner blood-vessel wall surface area for lymphocyte ingress from the blood into the synovium, and diminish the production of chemoattractants by the endothelial cells (3). Interestingly, EGF and HB-EGF have been shown to promote angiogenesis by increasing endothelial cell proliferation or migration (27–30). To determine whether erlotinib affects neoangiogenesis in CIA, we quantified the number of blood vessels per square millimeter in the ankle of mice treated with vehicle or erlotinib, by staining paw sections for von Willebrand factor. We found that the attenuation of CIA was associated with reduction in pannus formation (Fig. 2C, 2D). We therefore tested erlotinib’s effect on EGF-induced proliferation of synovial fibroblasts.

**FIGURE 2.** Erlotinib treatment ameliorates CIA. Following the development of arthritis, DBA1/J mice with CIA were randomly enrolled in a treatment group when they reached a mean visual arthritis score between 2 and 4. Mice were administered vehicle (n = 10), 10 mg/kg erlotinib (n = 12), or 50 mg/kg (n = 12) erlotinib twice daily by oral gavage. (A) Arthritis severity was assessed using a visual arthritis scoring system and (B) caliper measurements of paw thickness. Data represent one experiment of at least three independent experiments. (C) Representative images of paw sections and (D) blinded histological scores of synovitis, pannus formation, and bone and cartilage erosion. Scale bars, 300 μm. Groups were compared at each time point using a Mann–Whitney analysis comparing erlotinib-treated mice to vehicle-treated mice. Error bars indicate ± SEM. *p < 0.05, **p < 0.01.

COX-2 inhibitors can reduce swelling and pain in the joints of RA patients (31), and COX-2 expression is significantly greater in endothelial cells in RA synovium than in osteoarthritis synovium (32). Moreover, angiogenesis is dependent on COX-2 activity, as COX-2–specific inhibitors strongly reduce tube formation (33).
Previous studies have indicated that EGF induces COX-2 expression in RA synovial fibroblasts (21). We found that erlotinib inhibits the EGF-induced expression of COX-2 in HUVEC, suggesting that erlotinib may be reducing angiogenesis in vivo by modulating COX-2 expression in endothelial cells (Fig. 4C).

Erlotinib inhibited the EGF-induced phosphorylation of EGFR, as well as the EGF-induced phosphorylation of Akt and Erk1/2 in HUVEC (Fig. 4E), signifying that erlotinib suppresses HUVEC proliferation and COX-2 expression by inhibiting EGFR signaling. Erlotinib and PD153035 did not induce LDH release after 24 h treatment (Supplemental Fig. 4B), indicating that their suppression of HUVEC proliferation is not due to cell death.

**Erlotinib reduces osteoclastogenesis**

RA and CIA are characterized by the progressive destruction of bone and cartilage in the synovial joints (34, 35). This destruction is mediated by osteoclasts, which resorb mineralized bone and cartilage (4). Numerous osteoclasts are found in and adjacent to the inflamed synovium and are thought to derive from monocyte/macrophage lineage cells in the synovium (4). Because erlotinib treatment reduced the erosion of bone and cartilage in the joints of...
mice with CIA (Fig. 2), we compared the number of osteoclasts in the paws of CIA mice treated with vehicle and those treated with erlotinib. To this end, we performed immunohistochemical analysis for the expression of tartrate-resistant acid phosphatase (TRAP), a characteristic of osteoclasts. As with cartilage and bone erosion, there were more TRAP-positive cells in vehicle-treated than in erlotinib-treated mice. In fact, erlotinib reduced the number of TRAP-positive cells in a dose-dependent fashion (Fig. 5A). We next asked whether erlotinib could directly reduce the in vitro formation of osteoclasts, which we defined as TRAP-positive cells with three or more nuclei. Erlotinib significantly reduced the number of osteoclasts formed from bone marrow-derived monocytes; it also reduced the size of the osteoclasts (Fig. 5B–D). Erlotinib treatment significantly decreased the expression of four genes characteristic of osteoclasts: Acp5, which encodes TRAP; Ctsk, which encodes cathepsin K; Itgb3, which encodes β3-integrin; and Nfatc1, which encodes NF of activated T cells, cytoplasmic 1 (Fig. 5E) (36). Erlotinib treatment also reduced the expression of several MMPs, including Mmp3, Mmp9, and Mmp14, which mediate breakdown of the nonmineralized parts of the bone (Fig. 5E). Moreover, treatment with erlotinib significantly decreased osteoclast-mediated bone resorption (Fig. 5F) and did not alter LDH release (Supplemental Fig. 4C). This indicates that erlotinib inhibits the formation of osteoclasts from mononuclear cells. Taken together, this showed that EGFR inhibition reduces osteoclastogenesis.

TNF promotes osteoclastogenesis both directly and indirectly by promoting RANKL expression and binding TNF-α receptor type 1 on osteoclasts (4). To determine whether EGF promotes osteoclastogenesis directly, we treated the bone marrow-derived monocytes with EGF in the presence of osteoclast differentiation media containing a reduced concentration of RANKL, and then measured TRAP enzymatic activity and quantified the number of osteoclasts formed. A reduced concentration of RANKL was used to...
for these experiments because suboptimal osteoclast formation was required to discriminate the effects of EGF. EGF significantly increased the cells’ TRAP activity and the number of osteoclasts formed, suggesting that it promotes osteoclastogenesis. Moreover, concurrent treatment with erlotinib blocked the increase in TRAP activity and formation of osteoclasts induced by EGF, and partially blocked the TRAP activity induced by RANKL alone (Fig. 5G, 5H).

EGF induced the phosphorylation of EGFR, Akt, and Erk1/2 in osteoclasts, and this was reduced by treatment with erlotinib and PD153035 (Fig. 5I), suggesting that erlotinib suppresses osteoclastogenesis by inhibiting EGFR-induced gene expression. FOS is a member of the AP-1 family of transcription factors and is required for osteoclast formation (37). RANKL activates c-Fos transcription (37), possibly by transactivating EGFR (38). Moreover, EGFR signaling independently upregulates c-Fos expression in HeLa cells (39). We therefore tested the effect of erlotinib on monocytes incubated with differentiation media containing M-CSF and RANKL. We found that the osteoclast differentiation media caused a strong upregulation of Fos mRNA expression at 6 h, and that this was reduced by erlotinib (Fig. 5J). Given that FOS is necessary for osteoclast development (37), inhibiting FOS may be one way in which erlotinib reduces osteoclastogenesis.

Discussion

In this study, we show that EGF levels are abnormally high in the serum of RA patients, and that EGFR is both highly expressed and activated in synovial tissue from RA patients and from mice with autoimmune arthritis. Moreover, we find that the EGFR inhibitor erlotinib attenuates autoimmune arthritis in mice, reducing synovitis, pannus formation, and cartilage and bone erosion in their synovial joints. Erlotinib-induced attenuation of autoimmune arthritis was associated with a reduction in number of osteoclasts and blood vessels formed in the mouse paws, and erlotinib directly inhibited the formation of osteoclasts and the proliferation of endothelial cells in vitro, as did a distinct EGFR inhibitor. Erlotinib also inhibited the proliferation and cytokine production of synovial fibroblasts in vitro, an effect that may explain its ability to reduce pannus formation and synovitis in vivo.

Previous findings are conflicting as to which EGFR ligand is upregulated in RA. Studies of bone marrow-derived mononuclear cells and synovial fluid have implicated EGF, TGF-α, and amphiregulin in RA (9, 12, 40, 41). However, we find that only levels of EGF and betacellulin, and not TGF-α, HB-EGF, or amphiregulin, are higher in serum from RA patients than in serum from healthy individuals. This suggests that the exact EGF ligand involved in RA may differ between serum and synovial fluid, or may depend on RA subtype, disease duration, or the treatment regimen. Although we focused on EGF in this study, it will be interesting to further define the activity of betacellulin in RA. Betacellulin is known to promote angiogenesis, indicating that it may promote the growth of the synovium (42).

Previous studies found that EGFR is expressed on RA fibroblast cell lines and on the vascular endothelial cells and subsynovial fibroblasts of certain RA patients (9, 10). In this study, we show that EGFR is not only expressed but also activated in RA and CIA synovium. Furthermore, we confirm that EGFR is expressed and can be transactivated by EGF in cultured synovial fibroblasts.

Our finding that erlotinib, an EGFR inhibitor that is Food and Drug Administration approved for the treatment of cancer, attenuated CIA complements a recent report indicating that soluble herstatin, which inhibits the dimerization of ErbB receptors, attenuates CIA (6). Taken together, these findings suggest that inhibition of EGFR, and possibly ErbB2 (which is a frequent binding partner of EGFR), may provide benefit in RA.

Amphiregulin has been shown to increase the proliferation of RA synovial fibroblasts and to increase their expression of VEGF, IL-8, GM-CSF, and IL-6 (9, 40). EGF on its own was found to have little effect on synovial fibroblasts, but to synergize with TNF and IL-1β to increase mRNA expression of MMPs and proinflammatory molecules (19). We find that EGF alone can in fact induce the proliferation of synovial fibroblasts in a dose-dependent manner, an effect that could promote the growth of the pannus in RA. Moreover, we demonstrate that EGF alone can induce the production of IL-8, VEGF, MMP-3, and MCP-1 protein by RA synovial fibroblasts, and that concurrent EGFR inhibition with erlotinib or PD153035 reduces the production of these factors. Thus, erlotinib may indirectly have widespread effects on RA through its actions on RA synovial fibroblasts. These include decreasing IL-8– and MCP-1–induced neutrophil and monocyte migration into the joint space (23, 24), decreasing angiogenesis driven by VEGF (22), and reducing cartilage destruction promoted by MMP-3 (25).

RA synovium contains significantly greater numbers of blood vessels than does osteoarthritis synovium (26). In this study, we demonstrate that erlotinib reduces the number of blood vessels in CIA and that this may occur through both direct and indirect mechanisms. Erlotinib may directly reduce angiogenesis by impeding endothelial cell proliferation and COX-2 expression, and indirectly reduce angiogenesis by decreasing VEGF production by RA synovial fibroblasts.

RA and CIA are characterized by the progressive destruction of bone and cartilage in the synovial joints, a process mediated by osteoclasts (34, 35). Osteoclast development is driven by excessive production of RANKL and TNF in the RA synovium, which interact with their receptors on monocytes and macrophages driving osteoclast formation through the expression of transcription factors, such as FOS of the AP-1 complex and NFATc1 (4). EGF and EGFR may also promote bone destruction in RA, as bone formation is abnormal in EGFR-deficient mice, suggesting that EGFR is important for osteoclast formation (43). The EGFR inhibitors AG1478 and PD153035 have been shown to reduce osteoclast formation (38, 43); in this study, we show that EGFR inhibition with erlotinib also reduces osteoclast formation. EGFR inhibition reduced the number of osteoclasts formed, as well as their size, osteoclast-specific gene expression, and bone resorption capacity. Moreover, we demonstrate that EGFR increases the TRAP enzymatic activity and number of osteoclasts formed during low-RANKL conditions. This indicates that EGF, similar to TNF, promotes osteoclast activity in RA and CIA. Erlotinib reduced the osteoclast activity induced by EGF as well as that induced in the absence of added EGF. Furthermore, we demonstrate that erlotinib acts on osteoclasts by reducing EGF-induced phosphorylation of EGFR, Erk, and Akt, as well as RANKL-induced FOS expression. EGF may therefore supplement the transactivation of EGFR by RANKL and thereby promote osteoclast formation. This is important because it indicates that EGFR, in addition to RANK, might be a beneficial target to reduce bone loss in RA.

Taken together, our findings suggest that targeting EGFR has potential as a novel therapeutic strategy for RA. Rational targeting of EGFR inhibitors to specific phases of RA, limiting the duration of dosing, and combining EGFR inhibitors with other disease-modifying agents may be important in maximizing the benefit of EGFR inhibitors in RA. Patients with early, active RA may benefit most from EGFR inhibitor therapy. Patients with undifferentiated arthritis who go on to develop RA exhibit a distinct and transient increase in EGF expression in synovial fluid (44). This
suggests that early in the course of arthritis there may be a window of opportunity where EGFR inhibition could be beneficial in those patients with significantly heightened EGFR levels. EGFR levels may also correlate with disease activity and severity. EGFR levels in synovial fluid correlated with C-reactive protein and IgM levels in RA patients (12). High pretreatment levels of EGFR and MCP-1 distinguished patients who responded to etanercept therapy (45). Thus, as disease progresses, EGFR inhibition may continue to be of benefit to RA patients with more destructive disease courses. EGFR inhibitors such as erlotinib are known to cause adverse side effects, for example, rash and diarrhea (13), which make them less amenable to treating chronic, nonterminal diseases such as RA. However, several treatment strategies may increase the tolerability and efficacy of EGFR inhibitor therapy. First, pulsed, rather than chronic, therapy may suffice during early disease or during a disease flare when EGFR levels appear to peak. Second, patients with high levels of EGFR ligands in their serum may be specifically targeted for EGFR inhibitor therapy. Third, next-generation EGFR inhibitors being developed for the treatment of cancer may have a better therapeutic index. These include agents that bind EGFR irreversibly, target multiple ErbB family members, and inhibit additional kinases receptors such as those for VEGF and fibroblast growth factor, which are known to drive disease (46).

In conclusion, we show that EGFR inhibition using erlotinib reduces the severity of autoimmune arthritis in mice. The mechanism of action appears to be through inhibition of synovial fibroblasts, endothelial cell, and osteoclast inflammatory and degradative responses. Our findings demonstrate the importance of EGFR in the pathogenesis of autoimmune arthritis, and they provide evidence that EGFR, a molecule long targeted in cancer, may be a therapeutic target in RA.

Acknowledgments

We thank members of the Robinson laboratory for many rewarding discussions. Lauren Labeye, Orr Sharpe, and Yann Chong Tan particularly aided in figure development, Western blots, and PCR troubleshooting discussions. Lauren Lahey, Orr Sharpe, and Yann Chong Tan particularly provide evidence that EGFR, a molecule long targeted in cancer, reduces the severity of autoimmune arthritis in mice. The mechanism of action appears to be through inhibition of synovial fibroblasts, and inhibit additional kinases receptors such as those for VEGF and fibroblast growth factor, which are known to drive disease (46).
