IRF4 is a transcription factor from the IRF factor family that plays pivotal roles in the differentiation and function of T and B lymphocytes. Although IRF4 is also expressed in dendritic cells (DCs) and macrophages, its roles in these cells in vivo are not clearly understood. In this study, conditional knockout mice that lack IRF4 in DCs or macrophages were generated and infected with \textit{Leishmania major}. Mice lacking DC expression of IRF4 showed reduced footpad swelling compared with C57BL/6 mice, whereas those lacking IRF4 in macrophages did not. Mice with IRF4-deficient DCs also showed reduced parasite burden, and their CD4\(^+\) T cells produced higher levels of IFN-\(\gamma\) in response to \textit{L. major} Ag. In the draining lymph nodes, the proportion of activated CD4\(^+\) T cells in these mice was similar to that in the control, but the proportion of IFN-\(\gamma\)-producing cells was increased, suggesting a Th1 bias in the immune response. Moreover, the numbers of migrating Langerhans cells and other migratory DCs in the draining lymph nodes were reduced both before and postinfection in mice with IRF4 defects in DCs, but higher levels of IL-12 were observed in IRF4-deficient DCs. These results imply that IRF4 expression in DCs inhibits their ability to produce IL-12 while promoting their migratory behavior, thus regulating CD4\(^+\) T cell responses against local infection with \textit{L. major}. IRF4 in Dendritic Cells during Leishmania Infection

IRF4−/− DCs to prime T cells in IRF4−/− mice, because T cell function is also IRF4 dependent and is impaired in IRF4−/− mice.

We previously reported that, after s.c. infection with L. major into the footpad, IRF4−/− mice show significantly reduced footpad swelling 2–6 wk postinfection but show worsening of footpad swelling and a greater extent of infection later (16). The cell type responsible for the reduction of the lesion was not clear. In this study, we examined the possibility that IRF4 deficiency in macrophages or DCs causes enhanced immunity against L. major infection by using conditional gene knockout mice that lack IRF4 in macrophages or DCs. The study showed that IRF4 deficiency in DCs induces early and enhanced Th1-biased anti-Leishmania CD4+ T cell responses and causes a lesser degree of footpad swelling and reduced parasite burden. Recruitment of migratory DCs (mDCs) to the draining LNs also was reduced, but IRF4-deficient DCs produced increased levels of IL-12, suggesting that a higher level of IL-12 production from DCs induced enhanced Th1 immune responses against L. major.

Materials and Methods

Animals

Mice containing loxP-flanked Irf4 alleles (Irflflo) were kindly provided by Dr. U. Klein (Columbia University, New York, NY) (24). CD11c-Cre mice (25) were purchased from The Jackson Laboratory (Bar Harbor, ME). B6.129P2-Lys <tm1crlf>o > (LysM-Cre) mice (26) were provided by the Riken BioResource Center through the National Bio-Resource Project of the Ministry of Education, Culture, Sports, Science, and Technology, Japan. Irflflo mice were crossed with CD11c-Cre or LysM-Cre mice to generate IrflfloCD11c-Cre+ or IrflfloLysM-Cre mice, respectively. IRF4−/− mice were previously described (11). OT-II and OT-I transgenic mice expressing TCR specific for OVA323–339/IAb and OVA257–264/Kb, respectively, were provided by Dr. H. Kosaka (Osaka University, Osaka, Japan) (27, 28). B6.129P2-Lys <tm1crlf>o > (LysM-Cre) mice (26) were provided by the Riken BioResource Center through the National Bio-Resource Project of the Ministry of Education, Culture, Sports, Science, and Technology, Japan. Irflflo mice were crossed with CD11c-Cre or LysM-Cre mice to generate IrflfloCD11c-Cre+ or IrflfloLysM-Cre+ mice, respectively.

mice) or in macrophages (Irf4fl/flLysM-Cre mice, respectively). Swelling of the footpad peaked at 3–4 wk postinfection with L. major and then gradually decreased and healed in control C57BL/6 mice, whereas swelling continued to increase in BALB/c mice, as described previously (Fig. 1A). In Irf4−/− mice with a C57BL/6 background, the degree of footpad swelling was lower than that in C57BL/6 mice during the 2–6 wk of infection, but it continued to increase afterward without healing, as described previously (16). The continued footpad swelling in the late stages of infection was likely due to the loss of cellularity in the draining LNs and enhanced apoptosis of T cells that do not express IRF4 (24), we determined expression in cells that were depleted of IRF4 (24), whereas only a small proportion of T cells, B cells, and macrophages expressed GFP (Fig. 1C). IRF4 expression was detectable in the DCs of naive Irf4−/− mice, but not Irf4fl/flCD11c-Cre mice, by intracellular staining with a specific mAb, whereas macrophages in both mice expressed IRF4 at similar levels (Fig. 1D). The majority of DCs, as well as T and B cells, remained GFP− in Irf4fl/+LysM-Cre mice (Fig. 1E).

Th1 responses against L. major are enhanced in Irf4fl/+CD11c-Cre mice

We examined the mechanism underlying the reduction of footpad swelling in Irf4fl/+CD11c-Cre mice. Production of IFN-γ by CD4+ T cells is critical for the control of infection with L. major (34, 35). However, a previous study (36) showed that CD4+ T cells from resistant C57BL/6 mice produce IL-4 transiently during the first week of L. major infection. Thus, we determined whether IFN-γ and IL-4 were produced by CD4+ T cells during L. major infection. Therefore, we obtained CD4+ T cells from the draining LNs at different time points postinfection and stimulated them with L. major Ag in the presence of wild-type DCs in vitro (Fig. 2A). The level of IFN-γ production was significantly higher in CD4+ T cells from Irf4fl/+CD11c-Cre mice than in control Irf4fl/fl mice until 3 wk postinfection. Six weeks postinfection, we did not observe any significant differences in specific IFN-γ production by CD4+ T cells. The production of IL-4 was detected in Irf4fl/+ mice at early time points postinfection, as previously described (35), but this response was barely detectable in CD4+ T cells from Irf4fl/+CD11c-Cre mice, suggesting that their Th1 bias began early in the infection. We next used cell surface expression of CD11a and CD49d as markers of activated Ag-specific CD4+ T cells, as reported in virus-infected mice (37). All CD4+ T cells producing IFN-γ in response to L. major Ag were enriched in the CD11a+CD49d+ population obtained from the LNs of infected mice (Fig. 2B). CD4+ T cells from the draining LNs were stained for surface markers and intracellular IFN-γ (Fig. 2C–F). Two weeks postinfection with L. major, the proportion of CD11a+CD49d+ CD4+ T cells increased by ∼10% in both Irf4fl/+CD11c-Cre and Irf4fl/+ mice, suggesting that clonal expansion of specific CD4+ T cells was not significantly affected by the absence of IRF4 in DCs. However, the proportion of IFN-γ-producing CD4+ T cells was significantly higher in Irf4fl/+CD11c-Cre mice, suggesting the Th1 bias of the response. We also determined parasite burden in the infected footpads. As expected, it was significantly reduced in Irf4fl/+CD11c-Cre mice compared with control Irf4fl/+ mice (Fig. 2G). Our results indicate that the Th1 immune response against L. major is enhanced in mice lacking IRF4 in DCs, beginning as early as 4 d after the infection, leading to the effective clearance of parasites.

To confirm our results of a Th1-biased immune response in Irf4fl/+CD11c-Cre mice, we performed a second, independent experiment using PHOC L. major expressing OVA (29). Irf4fl/+CD11c-Cre

- FIGURE 1. Irf4fl/+CD11c-Cre mice show reduced footpad swelling postinfection with L. major. (A and B) C57BL/6, BALB/c, Irf4−/−, Irf4fl/fl, Irf4fl/+CD11c-Cre, and Irf4fl/+LysM-Cre mice were infected in the left hind footpad with L. major promastigotes (5 × 106), and footpad swelling was measured every week until 9 wk postinfection. Graphs show mean ± SD. Data represent three independent experiments (4–5 mice/group) with similar results. (C and E) Expression of GFP in DCs (MHC II+CD11c− cells), T cells (CD3+ cells), B cells (CD19+ cells), and macrophages (Gr-1+CD11b+CD11c−F4/80+ cells) in the popliteal LN from Irf4fl/fl (filled graph), Irf4fl/+CD11c-Cre (C, line), and Irf4fl/+LysM-Cre (E, line) mice. The numbers indicate the proportions (%) of GFP+ cells in each cell type. (D) IRF4 staining in DCs (CD11c+CD86+ cells) and macrophages (Gr-1+CD11b+CD11c−F4/80+ cells) from LNs of Irf4fl/fl (filled graph), Irf4fl/+CD11c-Cre (black line), and Irf4fl/+ (dashed line) mice.
and Irf4<sup>fl/fl</sup> mice were transferred with CFSE-labeled OT-II CD4<sup>+</sup> T cells and infected with PHOC L. major (Fig. 3A). Three days later, the proportion of OT-II cells within the CD4<sup>+</sup> T cell population in the draining LNs of Irf4<sup>fl/fl</sup>CD11c-Cre mice was lower than that in Irf4<sup>fl/fl</sup> mice (Fig. 3B, 3C). However, the proliferation of OT-II cells, as determined by the diminution of CFSE, was similar in both groups (Fig. 3B, 3D). Production of IFN-γ in OT-II cells, as well as in the recipient CD4<sup>+</sup> T cell compartment, was higher in Irf4<sup>fl/fl</sup>CD11c-Cre mice (Fig. 3B, 3E). These results confirmed that the enhanced Th1 response in Irf4<sup>fl/fl</sup>CD11c-Cre mice is due to the lack of IRF4 expression in DCs and not in T cells. In the CD8<sup>+</sup> T cell compartment, postinfection with PHOC

FIGURE 2. Irf4<sup>fl/fl</sup>CD11c-Cre mice show Th1-biased immune responses against infection with L. major. (A) At different time points postinfection with L. major (4 d and 2, 3, and 6 wk), CD4<sup>+</sup> T cells from the draining LNs were cultured in the presence of splenic DCs from C57BL/6 mice and L. major Ag for 72 h. The amounts of IFN-γ and IL-4 in the supernatants were determined by ELISA. Graphs show mean ± SD. Representative data of three similar results are shown. (B) Two weeks postinfection with L. major, popliteal LN cells were prepared from C57BL/6 mice and stained for CD4, CD3, CD49a, and CD11a. CD11<sup>a−</sup>CD49d<sup>+</sup>CD4<sup>+</sup> T cells (DP) and CD11<sup>a+</sup>CD49d<sup>+</sup>CD4<sup>+</sup> T cells (DN) were FACS sorted from the popliteal LNs and cultured in the presence of DCs from uninfected C57BL/6 mice and crude L. major. The levels of IFN-γ in the supernatant were determined by ELISA. (C-F) Postinfection with L. major, right (uninfected) and left (infected) popliteal LN cells were prepared from Irf4<sup>fl/fl</sup> (Ctrl) and Irf4<sup>fl/fl</sup>CD11c-Cre (CKO) mice and stained as in (B). (C and D) Flow cytometry profiles of CD4<sup>+</sup> T cell gating, as well as CD49d versus CD11a expression of CD4<sup>+</sup> T cells, are shown. After culture for 4 h with ionomycin/PMA, the left LN cells were stained for cell surface markers, fixed, permeabilized, and stained for IFN-γ. (D) CD3 and IFN-γ profiles of total CD4<sup>+</sup> and CD11<sup>a−</sup>CD49d<sup>+</sup>CD4<sup>+</sup> cells (right panels). Summary of the proportions (%) of CD11<sup>a−</sup>CD49d<sup>+</sup> cells in total CD4<sup>+</sup> T cells (E) and the proportions (%) of IFN-γ<sup>+</sup> cells within total CD4<sup>+</sup> T cells and in CD11<sup>a−</sup>CD49d<sup>+</sup>CD4<sup>+</sup> T cells (F). The horizontal line represents the mean value in each group. (G) Two and three weeks postinfection. DNA from the left footpads (n = 3 mice/group) were subjected to real-time PCR, and the relative ratio of L. major to the G3PDH housekeeping gene was calculated. The horizontal line represents the mean value in each group. *p < 0.05, ND, not detectable.

FIGURE 3. OT-II cells transferred to Irf4<sup>fl/fl</sup>CD11c-Cre mice show Th1-biased responses to the infection with L. major-OVA. (A) Irf4<sup>fl/fl</sup> (Ctrl) and Irf4<sup>fl/fl</sup>CD11c-Cre (CKO) mice were adoptively transferred with CFSE-labeled CD4<sup>+</sup> T cells from OT-II mice (CD45.1) and were infected with PHOC L. major (L. major OVA) (5 × 10<sup>6</sup>) in the left hind footpad. Three days postinfection, LN cells were stimulated with ionomycin/PMA for 4 h and stained for CD3, CD4, CD45.1, and IFN-γ. OT-II cells were gated as CD4<sup>+</sup>CD<sup>3+</sup>CD<sup>45.1+</sup> cells (right panels). (B) CFSE versus IFN-γ profiles of OT-II cells and IFN-γ staining of recipient CD4<sup>+</sup> cells. The numbers in the flow cytometry data indicate the proportions (%) of each cell population. The proportion of OT-II cells within the CD4<sup>+</sup> T cell population (C) and the proportion of IFN-γ<sup>+</sup> cells in the OT-II and recipient CD4<sup>+</sup> T cell populations (E) are shown for Irf4<sup>fl/fl</sup> (Ctrl) and Irf4<sup>fl/fl</sup>CD11c-Cre (CKO) mice. (D) The proportions of OT-II cells that divided more than once were determined by CFSE dilution. In (D) and (E), data from two independent experiments with similar results (n = 2–3 mice/group) were pooled. *p < 0.05.
L. major, OVA-specific transgenic CD8+ T cells from Ifrd4fl/flCD11c-Cre mice were more abundant and showed higher proliferation and a higher proportion of IFN-γ production compared with those from Ifrd4fl/fl mice (Supplemental Fig. 1).

IRF4 is necessary for migration of DCs to draining LNs postinfection

We next examined the composition of DC subsets in the spleen and LNs. The proportion of CD4+ DC subsets was severely reduced in the spleens of Ifrd4fl/flCD11c-Cre mice compared with Ifrd4fl/fl mice, as we previously reported (Fig. 4) (13). In the LNs, DCs can be divided into two subpopulations according to the expression levels of MHC class II and CD11c: resident conventional DCs, which are MHC II+CD11c+, and mDCs, which are MHC IIbCD11cint (Fig. 4) (23, 38). Interestingly, the proportion of CD4+ DCs within conventional DC subpopulations in the LNs of Ifrd4fl/flCD11c-Cre mice was not significantly different from that in their controls. Thus, IRF4 is critical for the development of CD4+ DCs in the spleen but does not appear to be required for the development of CD4+ conventional DCs in the LNs. However, the proportion of mDCs in LNs was reduced in Ifrd4fl/flCD11c-Cre mice compared with that in Ifrd4fl/fl mice, whereas the proportion of conventional DCs was similar to that in their controls; this finding is consistent with a previous result showing defective migration of skin mDCs in Ifrd4−/− mice (Figs. 4, 5A–C) (23).

We next examined DC subpopulations in the draining LNs before and 3 d postinfection with L. major. The number of conventional DCs in the LNs of uninfected Ifrd4fl/flCD11c-Cre mice was not significantly different from that in Ifrd4fl/fl mice, and the number increased similarly postinfection (Fig. 5A, 5B). MHC II+CD11c+ mDCs (mDCs) can be divided into Langerin− mDCs, which include CD11b− and CD11b+ subsets, and Langerin+ mDCs, which include epidermal Langerhans cells and CD103+ dermal DCs (Fig. 5A) (23, 38). The number of mDCs in LNs of naive Ifrd4fl/flCD11c-Cre mice was significantly lower than that in Ifrd4fl/fl mice. Postinfection, the number of mDCs in LNs increased by ∼2-fold in control Ifrd4fl/fl mice, but the increase in mDCs in Ifrd4fl/flCD11c-Cre mice was modest (Fig. 5C). A similar pattern of reduction in DC numbers was observed in LNs before and postinfection in all subsets of mDCs, with the exception of CD103+ DCs, which had a very small absolute number (Fig. 5D). To determine the expression of IRF4 in each DC subset, we stained LN cells from naive and infected mice with subset-specific cell surface markers and intracellular IRF4. All conventional DC and mDC subsets in Ifrd4fl/fl mice expressed IRF4, and the level of expression did not change 1–3 d postinfection (Fig. 5E, data not shown). Because IRF4 promotes CCR7 expression, we measured the expression of CCR7 in mDC subsets (Fig. 5F) (23). As expected, the majority of mDC subsets in Ifrd4fl/flCD11c-Cre mice, in particular Langerin− DCs, expressed CCR7 at levels lower than those in Ifrd4fl/fl mice.

We also examined skin DC populations during homeostasis and postinfection. In the epidermis, the proportions of MHC II+ cells and Langerhans cells were similar between Ifrd4fl/fl and Ifrd4fl/flCD11c-Cre mice both before and postinfection (Fig. 6A–C). In the dermis, the proportions of MHC II+ cells and Langerhans cells also were not significantly different between Ifrd4fl/flCD11c-Cre and Ifrd4fl/fl mice. However, the proportions of CD11b+ and CD103+ dermal DCs in Ifrd4fl/flCD11c-Cre were significantly higher than those in Ifrd4fl/fl mice both before and postinfection (Fig. 6D–F). These data suggest that the development of epidermal and dermal DCs is impaired in Ifrd4fl/flCD11c-Cre mice, and that these cells stay in the skin postinfection as a result of defects in their ability to migrate. Taken together, our model using conditional knockout mice that lack IRF4 in DCs showed that IRF4 plays an important role in the migration of mDCs in the steady-state and postinfection, consistent with the observation in a previous study using Ifrd4−/− mice (23).

IRF4 inhibits IL-12 production by mDCs

IL-12 is a key cytokine for the induction of Th1 immune responses and IFN-γ production postinfection with L. major. We hypothesized that IL-12 production by IRF4-deficient DCs is responsible for this higher Th1 induction in Ifrd4fl/flCD11c-Cre mice. Draining LN cells from Ifrd4fl/flCD11c-Cre and Ifrd4fl/fl mice were collected 3 d after the infection and measured for IL-12 production by intracellular cytokine staining. All subsets of IRF4-deficient mDCs, with the exception of minor CD103+ DCs, produced higher amounts of IL-12 compared with Ifrd4fl/fl mice (Fig. 7A, 7B). To confirm the role of IL-12 in the enhanced protective immunity observed in Ifrd4fl/flCD11c-Cre mice, IL-12 was neutralized in vivo using an anti–IL-12 mAb (Fig. 7C). Although parasite burden in Ifrd4fl/flCD11c-Cre mice was lower than that in Ifrd4−/− mice without IL-12 blockade, both groups showed similarly high levels of parasite burden when IL-12 activity was neutralized in vivo. We also examined the expression of costimulatory molecules in IRF4-deficient and control DC subsets. All of these DC subsets expressed CD80, CD86, and CD40 at high levels in both Ifrd4fl/flCD11c-Cre and Ifrd4fl/fl mice (data not shown). These results suggest that DCs pro-

FIGURE 4. The numbers of CD4+ conventional DCs are reduced in the spleen but not in LNs of Ifrd4fl/flCD11c-Cre mice. Cells were prepared from spleen (A, B, E) and popliteal LNs (C, D, F, G) of Ifrd4fl/fl (Ctrl) and Ifrd4fl/flCD11c-Cre mice (KO) and were stained for MHC class II, CD11c, CD4, and CD8. CD4 versus CD8 expression of splenic DCs (CD11c+MHC II+), migratory LN DCs (mDCs; MHC IIbCD11cint), and conventional LN DCs (cDCs; MHC II+CD11c+) is shown. The proportion (%) of each subpopulation is indicated. *p < 0.05.
duce higher levels of IL-12 early postinfection in Irf4<sup>fl/fl</sup>CD11c-Cre mice, leading to Th1-biased immune responses.

**Discussion**

In this study, we evaluated the role of IRF4 expressed in macrophages and DCs during infection with *L. major*. Macrophages are definitive host cells for survival and replication of *Leishmania* parasites and they are also one of the major effector cells. We reported previously that IRF4<sup>−/−</sup> macrophages produce higher levels of cytokines, such as TNF-α, IL-12, and IL-6, in response to TLR signaling (20, 21). However, in this study, IRF4-deficient macrophages did not affect the course of the infection with *L. major*. The production of IL-12 by infected macrophages was reported to be inhibited by resident *L. major* parasites (3); thus, the effect of IRF4 deficiency in macrophages may not have been apparent following *L. major* infection. DCs are the main producers of IL-12, which is critical for Th1 differentiation and IFN-γ production by CD4<sup>+</sup> T cells during infection with *L. major* (39). In our study, IRF4 deficiency in DCs enhanced the protective Th1 immunity against *L. major* infection, leading to better clearance of parasites, thus suggesting that IRF4 expressed in DCs may play a regulatory role in the production of IL-12 in vivo. One caveat of this study is the leakiness of Irf4<sup>fl/fl</sup>CD11c-Cre mice. We observed small, but significant, proportions of lymphocytes and macrophages expressing GFP, indicating that these cells lack IRF4 (Fig. 1C). Therefore, a possibility that IRF4 expressed in a subpopulation of macrophages is involved in the protection cannot be completely excluded, although we think that it is less likely.

The proportion of Ag-specific CD4<sup>+</sup> T cells in the draining LNs of Irf4<sup>fl/fl</sup>CD11c-Cre and Irf4<sup>fl/fl</sup> mice, as judged by the proportion of CD11a<sup>hi</sup>CD49d<sup>+</sup> CD4<sup>+</sup> T cells, was not significantly different, suggesting that the levels of activation/proliferation of Ag-specific CD4<sup>+</sup> T cells were equivalent in both groups. However, CD4<sup>+</sup> T cells in Irf4<sup>fl/fl</sup>CD11c-Cre mice showed a strong Th1 bias as early as 4 d postinfection and during the peak response against *L. major*. These results were confirmed in experiments using mice transferred with OT-II cells and infected with OVA-expressing *L. major*. The expansion of OT-II cells, as evaluated by the diminution of CFSE, was not significantly different between Irf4<sup>fl/fl</sup>CD11c-Cre and control mice, whereas the proportion of OT-II cells in the draining LNs was lower in Irf4<sup>fl/fl</sup>CD11c-Cre mice. We speculated that this reduction was due to the reduced recirculation of OT-II cells to the LNs of Irf4<sup>fl/fl</sup>CD11c-Cre mice, in which the number of mDCs was reduced, because it was reported that lymphocyte recirculation is controlled by DCs expressing lymphotixin (40). Functionally, the IFN-γ response in OT-II cells
wider was than in Irf4−/−CD11c-Cre mice. These results collectively suggest that Ag-specific CD4+ T cells primed by IRF4-deficient DCs expand at levels similar to control, but their responses are more biased toward a Th1 type. Thus, IRF4 expression in DCs plays a pivotal role in priming Th1 cells.

We previously reported that the proportion of the CD11bhigh
CD4+ DC subset is severely reduced in the spleen of Irf4−/− mice (13). We confirmed that this population was also reduced in the spleens of Irf4−/−CD11c-Cre mice. However, the CD4+ DC subset was not reduced in the LNs of Irf4−/− or Irf4−/−CD11c-Cre mice compared with controls, suggesting that IRF4 is not essential for the development of CD4+ DCs in LNs. The differences in IRF4 dependency for the presence of splenic and LN CD4+ DCs suggest that these two DC subsets might be derived from different developmental pathways. Alternatively, the LN environment might compensate for the IRF4 dependency on the development, survival, or migration of CD4+ DCs. Recently, studies showed that the proportions of CD103+CD11b+ DCs in the lamina propria of the small intestine and mesenteric LNs, as well as CD24+CD11b+ DCs in the lung, are reduced in mice with IRF4-deficient DCs. These mice failed to support the development of Th17 cells after immunization or infection (41, 42). In these studies, IRF4 was shown to be required for the survival of a CD11b+ DC subpopulation in the intestine and the lung, rather than their development. Thus, the IRF4 dependency of DCs appears to differ depending on DC subtype and localization. Further study is required to clarify the role of IRF4 and other transcription factors in the development and homeostasis of different DC subtypes in different tissues.

Prior to infection, the numbers of resident DCs in the LNs of control and Irf4−/−CD11c-Cre mice were similar, and they increased similarly postinfection. However, the number of mDCs in Irf4−/−CD11c-Cre mice was lower than that in the control prior to infection, and it did not increase significantly postinfection. In the epidermis and dermis of Irf4−/−CD11c-Cre mice, the proportion of Langerhans cells was not reduced postinfection with L. major, but CD11b+ and CD103+ DCs were increased, suggesting that migration of these DC subsets from the skin to the draining LNs was impaired in the absence of IRF4. CCR7 expression was reduced in mDCs lacking IRF4, consistent with the reduced ability of these DCs to migrate to the LNs. While this study was in progress, Bajaña et al. (23) reported that migration of CD11b+ DCs, as well as Langerhans cells, from the dermis to LNs was impaired in Irf4−/− mice. Our study using Irf4−/−CD11c-Cre mice is consistent with their study and further shows that the defective migration of DCs occurs independently of the IRF4 defect in the lymphocyte compartment. Interestingly, priming of L. major–specific CD4+ T cells was not reduced in Irf4−/−CD11c-Cre mice, despite reduced migration of skin DCs to draining LNs. We speculate that the activation of CD4+ T cells during the early period after L. major infection depends on the resident DCs in the draining LNs, which receive soluble Leishmania Ag through the lymph conduit network, as shown previously (6), and, therefore, was not severely affected by the reduced migration of DCs from footpads.

IL-12 released by DCs plays a pivotal role in Th1 development and IFN-γ production in CD4+ cells (43). In Irf4−/−CD11c-Cre mice, DC subsets produced IL-12 at levels higher than that in the control during infection with L. major, which explains, at least in part, why CD4+ T cells are more prone to Th1 skewing in Irf4−/−CD11c-Cre mice. TLR delivers critical signals that induce IL-12 production in DCs during immune responses against infection with L. major. It was shown that MyD88−/−C57BL/6 mice produce reduced levels of IL-12 and exhibit lesions similar to Th2-prone susceptible BALB/c mice during infection with L. major (44). TLR2, TLR4, and TLR9 are suggested to be involved in the recognition of Leishmania molecules, and TLR9 appears to be the most important TLR required for the development of Th1 responses (45). We showed previously that IRF4 negatively regulates TLR signaling and production of proinflammatory cyto-
Kines, including IL-12 in macrophages (20, 21). Thus, it is likely that, similar to what is observed in macrophages, production of IL-12 in IRF4-deficient DCs during infection, leading to accelerated Th1-type CD4+ T cell responses. We examined the expression of IRF4 and IL-12 production in DC subsets in LNs. In contrast to splenic DCs that showed heterogeneous expression of IRF4 (13), all DC subsets in LNs showed IRF4 expression. IL-12 production was detected in all DC subsets, including resident and mDCs, in our intracellular cytokine-staining assay. The proportions of DCs producing IL-12 were significantly higher in the majority of IRF4-deficient mDC subsets compared with controls, consistent with the inhibitory role of IRF4 in TLR signaling. IL-12 production by resident DCs from Irf4fl/flCD11c-Cre mice was not significantly different from that in Irf4fl/fl mice. However, CD4+ T cells showed strong Th1-biased protective immunity against L. major. Perhaps, enhanced production of IL-12 by mDCs established a Th1-biased environment. In this study, we showed that IRF4 expressed in DCs is inhibitory for their IL-12 production in vivo during L. major infection and that it plays a pivotal role in regulating Th1 differentiation of CD4+ T cells. Bajana et al. (23) reported that IRF4 is critical for the CCR7-mediated migration of CD11b+ DCs from the dermis to LNs. Recent studies (41, 42) suggest that IRF4 in DCs is critical for the survival of a subset of CD11b+ DCs in the lamina propria of the intestine and lung, as well as mesenteric LNs, and support Th17 differentiation after immunization or infection. Taken together, these studies highlight critical roles for IRF4 in controlling DC homeostasis and function and, thus, regulating functional differentiation of CD4+ T cells. IRF4 in DCs is required for Th17 development but is inhibitory for Th1 development of CD4+ T cells. It would be interesting to examine whether IRF4 expressed in DCs also affects differentiation of CD4+ T cells to other lineages, including follicular Th and induced Tregs, in different models. Furthermore, previous studies (46, 47) showed that the expression and function of IRF4 can be modulated by PGE_2 and immunophilin FKBP52, respectively. Thus, IRF4 expressed in DCs could be a target of drug-mediated immune modulation. Further study is required to fully elucidate the role of IRF4 in
regulating DC subtypes and the immune responses that they regulate. This will be of particular importance when developing vaccines or novel strategies that modulate immune responses.

Acknowledgments

We thank Dr. U. Klein for kindly providing Ifng-deletion mice, Dr. H. Kosaka for OT-II and OT-I mice, Dr. D.F. Smith for PHOC L. major, N. Kawamoto for technical assistance, and C. Urita for help with the cell sorting.
