Lack of Peripheral Memory B Cell Responses in Recovered Patients with Severe Acute Respiratory Syndrome: A Six-Year Follow-Up Study

Fang Tang,*† Yan Quan,* Zhong-Tao Xin,§ Jens Wrammert,¶ Mai-Juan Ma,* Hui Lv,# Tian-Bao Wang,# Hong Yang,* Jan H. Richardus,** Wei Liu,* and Wu-Chun Cao*

Six years have passed since the outbreak of severe acute respiratory syndrome (SARS). Previous studies indicated that specific Abs to SARS-related coronavirus (SARS-CoV) waned over time in recovered SARS patients. It is critical to find out whether a potential anamnestic response, as seen with other viral infections, exists to protect a person from reinfection in case of another SARS outbreak. Recovered SARS patients were followed up to 6 y to estimate the longevity of specific Ab. The specific memory B cell and T cell responses to SARS-CoV Ags were measured by means of ELISPOT assay. Factors in relation to humoral and cellular immunity were investigated. Six years postinfection, specific IgG Ab to SARS-CoV became undetectable in 21 of the 23 former patients. No SARS-CoV Ag-specific memory B cell response was detected in either 23 former SARS patients or 22 close contacts of SARS patients. Memory T cell responses to a pool of SARS-CoV S peptides were identified in 14 of 23 (60.9%) recovered SARS patients, whereas there was no such specific response in either close contacts or healthy controls. Patients with more severe clinical manifestations seemed to present a higher level of Ag-specific memory T cell response. SARS-specific IgG Ab may eventually vanish and peripheral memory B cell responses are undetectable in recovered SARS patients. In contrast, specific T cell anamnestic responses can be maintained for at least 6 y. These findings have applications in preparation for the possible reemergence of SARS. The Journal of Immunology, 2011, 186: 7264–7268.

Six years have passed since the outbreak of severe acute respiratory syndrome (SARS). Previous studies indicated that specific Abs to SARS-related coronavirus (SARS-CoV) waned over time in recovered SARS patients. It is critical to find out whether a potential anamnestic response, as seen with other viral infections, exists to protect a person from reinfection in case of another SARS epidemic? Previous studies indicated that specific Abs to SARS-related coronavirus (SARS-CoV) waned over time. (4–9) However, disappearance of anti–SARS-CoV Abs does not necessarily indicate loss of protection. As is well known, an efficient line of defense against viral reinfection consists of three key components: preexisting Abs, memory B cells, and memory T cells. Humoral memory (i.e., secretion of specific protective Abs over long periods in the apparent absence of the Ag) provides the host with a first line of defense against reinfection, constituting protection against a range of pathogens (10). For SARS-CoV infection, however, only a limited duration and limited level of humoral response could be elicited after natural infection (4, 5). In the absence of another SARS outbreak, we cannot deduce whether lower or even undetectable levels of specific Abs would be adequate to protect a person from reinfection by a potential anamnestic response.

As seen with other viral infections such as measles and hepatitis A, memory B cells play an essential role in driving the rapid anamnestic Ab response that occurs after reexposure to Ag, even after levels of circulating Abs disappear, which can either completely prevent disease or greatly alleviate the severity of clinical manifestation (10). Human memory B cell response was supposed to be long-lived, but different viral infections lead to variety in the longevity of memory cells. Specific memory B cell response to variola virus could last for >50 y in immunized individuals (11). Patients surviving smallpox were thought to obtain life-long protection against reinfection (12, 13). It is unclear whether a potential anamnestic B cell response exists to protect a person from reinfection after reexposure to SARS-CoV. Of course, T cell responses are known to play their roles in protection against many viral infections and in supporting an anamnestic Ab response, because the anamnestic response of B cells depends on Ag-specific memory CD4+ T cells for rapid reactivation and differentiation into Ab-secreting cells (14). Cellular immune responses to SARS-CoV were confirmed in both SARS patients and experimental animals (15, 16). Memory T cell responses were detected in patients recovering from SARS 1, 2, and even 4 y later, although with a clear decline over time (17–19). Whether the memory T cell...
response will be maintained at a detectable level thereafter re-
mains to be investigated.

The objectives of this study were to estimate the longevity of
specific Ab against SARS-CoV, to measure the memory B cell and
T cell responses in patients recovering from SARS, and to identify
the factors possibly correlated with the specific immune responses.

Materials and Methods

Subjects

Three groups of subjects were included; that is, a cohort of convalescent
SARS patients, close contacts of former SARS patients, and healthy
controls. The SARS patients were originally seen at one hospital in Beijing,
which had been described in our previous studies (4, 6). All the patients
were clinically diagnosed according to the World Health Organization
criteria (20) and then confirmed by serological tests. The recovered
patients were followed for 6 y. Physical examination as performed and
sera samples were collected at each visit. At the last visit (6 y after dis-
ease), PBMCs were also isolated from anticoagulated blood by Ficoll-
Hypaque density gradient centrifugation. The mean (±SD) age of the
recruited 23 patients was 31.7 ± 8.3 y (range, 20–51 y), and 17 (73.9%) were
females. Nine patients had underlying disease, including tuberculosis
(n = 2), hepatitis B (n = 2), alcoholic liver disease (n = 1), hypertension
(n = 2), vascular disease (n = 2), diabetes (n = 1), and hyperlipemia
(n = 1), and seven patients had a severe illness according to revised criteria (20).
The 22 close contacts (10 males and 12 females, ages 26–49 y) were
health care workers that had been in contact with confirmed SARS patients
in 2003. The 20 healthy controls (10 males and 10 females, ages 21–40 y)
were individuals from a nonepidemic area who had never been exposed to
SARS-CoV. All the volunteers in the two control groups were negative
for IgG Ab to SARS-CoV. PBMCs were obtained from each subject and used
for the assays of B and T cell responses.

The study was approved by the Chinese National Center for AIDS
Prevention and Control Institutional Review Board, and written informed
consent was obtained from all the cases and controls.

IgG Ab evaluation

The sera were separated and tested for their anti–SARS-CoV IgG response
using commercially available ELISA kits (no. S20030003; BJI-GBI
Biotechnology, Beijing, China) as described previously (7). The 96-well
polystyrene microtiter plates were coated with 10 μg/ml pure coronavirus
Ag (SARS-CoV BJ01 strain, accession no. AY278488 in GenBank)
for detection. The inactivated SARS-CoV was able to preserve the immuno-
genicity of S protein including its major neutralizing domain according to
the previous study (21). The ELISA process was strictly performed exactly
as described in the previous study (7), by the same group using the same
kit, to ensure the consistency of the multiple tests.

Memory B cell measurement

PBMCs from three groups of subjects were plated in 24-well dishes at 5 ×
10⁵ cells/well in R-10 supplemented with a mix of polyclonal mitogens: 1/
100,000 PWM extract (Sigma-Aldrich, St. Louis, MO), 6 μg/ml phos-
phomycin (Sigma-Aldrich), 0.05 μg/ml lipo-204 μg/ml goat anti-human IgG
(Cowen BioTech, Beijing, China) as described previously (7). The 96-well
poly styrene microtiter plates were coated with 10 μg/ml pure coronavirus
Ag (SARS-CoV BJ01 strain, accession no. AY278488 in GenBank)
for detection. The inactivated SARS-CoV was able to preserve the immuno-
genicity of S protein including its major neutralizing domain according to
the previous study (21). The ELISA process was strictly performed exactly
as described in the previous study (7), by the same group using the same
kit, to ensure the consistency of the multiple tests.

Memory T cell measurement

Based on the fact that IFN-γ was the predominant cytokine produced by
T cells after stimulation with peptides (18), we performed IFN-γ ELISPOT
assay with overlapping synthetic peptides (total 20 peptides, 17mers over-
lapping by 9 aa residues) spanning the immunodominant site IV S protein
of SARS-CoV. As described in the previous publication (23), the used pep-
tide pools, which overlap the site IV sequence in the S protein, were
identified to react with the convalescent sera of former SARS patients but
without none of the samples from healthy blood donors, suggesting the justifica-
tion for their use in eliciting SARS-CoV specific memory T cell response.

ELISPOT assay kit for IFN-γ was purchased from BD Biosciences and per-
formed as instructed. Briefly, 96-well plates (Millipore) were coated with
anti-IFN-γ capture Ab at 4°C overnight. The plates were washed three times
before blocking with complete culture medium. Fresh PBMCs were
plated at 2 × 10⁶ cells per well in triplicate. Peptides and stimulatory
mAbs to CD28 and CD49d were added. PBMCs stimulated with PHA were
used as positive controls, and PBMCs not stimulated were used as nega-
tive controls. After incubation for 16–20 h at 37°C in 6–8% CO₂, the su-
pernatants were harvested and assayed for IFN-γ production by ELISA
according to the manufacturer’s protocol (BD Pharmingen). The cells were
removed and incubated with biotinylated anti-human IFN-γ detection Ab
for 2 h at 37°C. After washing, wells were developed for 1 h with strep-
avidin–HRP and incubated with substrate reagent according to the man-
ufacturer’s protocol. The frequency of IFN-γ–producing cells was cal-
culated as the number of spots/number of total PBMCs per well and was
adjusted as the number of IFN-γ–producing cells/10⁵ PBMCs. The number of spots in negative control wells was at a range of 0–5 spots.
Wells containing spot numbers greater than the mean ± 3 SD of three
negative control wells (no peptide) were regarded as positives in each
individual, provided that the total was >5 SFCs/million PBMCs to rule out
false positives where background was very low.

Statistical analysis

Before final analysis, Ab data were censored by excluding subjects who
were visited less than three times during the whole process. In the case of
undetectable Ab, an arbitrary value of 1:5 was assigned to allow for calcu-
lation of the geometric mean titer. Differences in continuous variables
levels or proportions were tested using t test, one-way ANOVA, or χ² test,
where appropriate. Non-parametric Spearman’s test was performed for
correlation analysis. Geometric means of memory cell levels were com-
pared between groups by t test of log-transformed values. A p value <0.05
was considered to be statistically significant. All the data were processed
using SAS version 9.1 (SAS Institute) and Microsoft Excel 7.0.

Results

Anti-SARS Ab evaluation

Six years postinfection, specific IgG Ab to SARS-CoV turned
undetectable in 21 of the 23 recovered patients with only 2 patients
maintaining low levels of IgG Ab. Fig. 1 shows the kinetics of IgG
Ab titers of the two patients by months since onset of SARS
symptoms in comparison with the changes in IgG Ab levels of
the patients as a whole. The IgG Ab of patient A was 1:256 when
discharged from the hospital and diminished gradually thereafter
to 1:20 at month 72 since disease onset, which followed a similar
pattern as that of the whole group of patients, whereas patient B
maintained a low (1:40) but stable level of specific IgG Ab during
the 6-y follow-up period.

Memory B cell responses to SARS-CoV

PBMCs from 23 recovered SARS patients, 22 close contacts, and
20 healthy controls were tested for B responses with PWM and

20 healthy controls were tested for B responses with PWM and

20 healthy controls were tested for B responses with PWM and

20 healthy controls were tested for B responses with PWM and
LACK OF MEMORY B CELL RESPONSES IN SARS PATIENTS

SARS-CoV Ag as stimulation, respectively (Fig. 2A). As a result, the nonspecific B cell responses, presented as the total of B cells producing IgG, were not significantly different (one-way ANOVA, p = 0.948) (Fig. 2B). When the PBMCs were stimulated with SARS-CoV Ag, no specific B cell response was detected in the patient group or close contact and healthy control groups (Fig. 2A). Two paired PBMC samples from two SARS patients in another SARS cohort, which were collected 3 mo postinfection and 3.5 y after recovery, were used to perform the same ELISPOT assays simultaneously. The positive specific B cell response in the acute samples and negative response in late samples further proved that the system was capable of detecting SARS-specific memory B cell responses (Supplemental Fig. 1).

Memory T cell responses to SARS-CoV

Memory T cell responses were tested using ELISPOT assay in 23 recovered SARS patients, 22 close contacts, and 20 healthy controls. When stimulated with PHA, PBMCs from the three groups presented high frequency of IFN-γ–forming cells (Fig. 3A), with no significant difference observed (one-way ANOVA, p = 0.556) (Fig. 3B). When stimulated with SARS-CoV peptides, 14 of 23 (60.9%) recovered patients demonstrated specific memory T cell responses (Fig. 3C). In contrast, neither close contacts nor healthy controls showed a detectable T cell response. The number of SFCs ranged from 1 to 216 with an average of 37 ± 51 per 2 × 10^5 PBMCs in the former SARS patients, which was significantly higher than those from close contacts (SFCs = 0) (one-way ANOVA, p = 0.001) (Fig. 3C). We then compared the memory T cell levels of the recovered patients in relation to the factors that might affect host immunity. No statistically significant difference of memory T cell response was observed between male and female patients or between high and low steroid dosage groups (Fig. 3D, 3E). The patients with comorbid conditions seemed to have a higher T cell response level than that of patients without comorbidity, but the difference was not significant (Fig. 3F). The patients presenting severe clinical manifestations showed significantly higher memory T cell responses to SARS-CoV than those of others (Fig. 3G, t = 2.222, p = 0.037). Because no SARS-specific memory B cell was detected and only two patients had detectable IgG Abs, the association between memory T and B cell responses could not be measured. We then compared peak serum IgG titers and memory T cell frequencies of each patient (Fig. 3H) and found no significant correlation between them (Spearman correlation analysis, r = 0.208, p = 0.392).

Discussion

Although 6 y have passed since the outbreak of SARS in 2003, there are still many unsolved mysteries and scientific problems regarding this emerging infectious disease. One of the major concerns is how long the protective immunity will be maintained in individuals after SARS-CoV infection. It is believed that both specific IgG Abs and neutralizing Abs are important to protect hosts from viral reinfection, often in combination with cellular immunity (24).

In this study, a group of serologically confirmed SARS patients were followed for 6 y to observe the dynamic changes in specific IgG Abs. As seen in our previous studies (4, 6), the humoral immunity continuously declined over time and eventually vanished in most patients. Only 2 of 23 patients maintained a low level of IgG Ab 6 y after disease onset. Numerous previous studies have demonstrated that the titers of neutralizing and IgG Abs are well correlated throughout the follow-up period (4, 6, 9). Although we did not test the neutralizing Ab to SARS-CoV in this study because the culture for SARS-CoV is restricted for the sake of biosafety, the IgG Ab could be a reliable indicator of neutralizing Ab for understanding the humoral response to SARS-CoV infection. The findings of these studies imply that naturally acquired humoral immunity of SARS patients persists for a limited period of time, which brings forward another question whether waning specific Abs would be adequate to protect a person from reinfection by a potential anamnestic response, as seen with many other viral infections. To answer the above question, we measured the memory B cell and T cell responses against SARS-CoV in former SARS patients.

To our knowledge, this is the first published study on memory B cell response to SARS-CoV and the first report of memory T cell response as long as 6 y after natural infection. In this study, no circulating SARS-CoV Ag-specific memory B cell response was

FIGURE 1. Dynamic changes in specific IgG Ab against SARS-CoV in patients who recovered from SARS. The geometric mean reciprocal titers (black line) are shown for the IgG Ab of the group of patients. The number of serum samples tested at each visit is given in the figure. The IgG titers of patient A (red line) and patient B (green line) are demonstrated.

FIGURE 2. Comparison of total IgG^+ memory B cell and SARS-CoV specific memory B cell response among 23 former SARS patients, 22 close contacts, and 20 healthy controls. A. Total IgG^+ and SARS-CoV Ag–specific memory B cells were measured and are shown as representative results from the former SARS patients, close contacts, and healthy controls. B. Total IgG^+ memory B cell counting in three groups; no significant difference was observed.
detected in recovered SARS patients by using the ELISPOT method. The peripheral memory B cell response was even not detected in the two patients who maintain low levels of specific IgG Ab. Also, we were able to demonstrate positive and negative SARS-specific memory B cell responses in two paired samples, thus verifying the negative results in the 6-y convalescent patients. The lack of specific memory B cell response in the patients 6 y after disease onset implies that SARS-CoV infection is different from many other viral infections in which memory B cells are able to produce sufficient Abs promptly in response to reexposure and also replenish long-lived plasma cells to maintain long-term Ab levels that can neutralize viruses. A representative example is that the memory B cells generated by smallpox vaccination could be detected even 40–50 y after immunization (25). In contrast, short-lived memory B cell responses have been observed in influenza and HIV infections, in which persistent low level of viral replication is not adequate to maintain specific memory B cells (26). In antiviral defense, B cells are supposed to play a central role by providing protective natural Abs in the first line, humoral memory Abs in the second line, and reactive memory B cells in the third line.

In the absence of chronic immune reactions, maintenance of humoral memory and most serum Abs are supposed to be derived from long-lived plasma cells of the bone marrow (27–29). Long-lived plasma cells in a human are thought to live for decades (30), which can totally provide alternative protection besides memory B cells. The current study only assessed polyclonal activation of memory B cells in vitro. Further studies are required to examine the memory B cells possibly residing in other parts of the body such as bone marrow and secondary lymphoid organs. However, the absence of peripheral memory B cells might reflect, to certain extent, the low or even undetectable level of memory B cell in bone marrow, as the latter seemed to be the major source of peripheral memory B cells.

Our results demonstrated that SARS-CoV–specific memory T cells persisted in peripheral blood of recovered SARS patients. In comparison with memory B cells, memory T cells are usually present with higher numbers and usually elicited in faster responses and better location (31), but they are not necessarily protective (32). Previous studies in animal models and clinical observation demonstrated that memory T cells did contribute to protective immunity against influenza viruses but could only be
attained in concert with the H1-specific plasma cells and memory B cells rather than memory T cells alone (14). B cell responses to influenza vaccination in HIV-infected individuals dropped with the decrease of CD4+ cells (33). The relative importance of memory B cells as well as long-lived plasma cells or memory T cells in protective immunity of SARS-CoV infection remains to be investigated.

In the study, we also found that patients with severe disease demonstrated increased memory T cell responses. Another study reported that the frequency of memory CD4+ T cells was significantly higher in patients with severe SARS in comparison with those with mild-to-moderate illness (17). The severe illness was also associated with a more robust IgG response (7, 9). An appealing and well-accepted explanation for these findings is that an overexuberant host response might be associated with worsening of disease and progressive lung damage (34, 35), yet this overreaction might not be a long-lasting one. The limitation of the study should be addressed. The matched samples were only available from two patients because of the difficulty in acquiring samples, therefore more convincing data should be obtained to demonstrate the lack of SARS-specific memory B cells long after infection. The lack of additional experiments, for example, the tests on memory B or T cell-type cytokines, purified B and T cells/ cell subsets, and so forth, due to the limited accessible samples, made further evaluation of immune response impossible. These two points are the major limitations of the study and should be addressed in future investigations.

In conclusion, specific IgG Ab to SARS-CoV eventually vanish in most SARS patients. Peripheral memory B cell responses are undetectable in all the patients. However, quite a portion of the patients maintain T cell memory even 6 y postinfection. Whether the T cell anamnestic response is adequate to protect a person from reinfecion requires further investigation. The findings are expected to have implications for disease management and surveillance in case of disease reemergence. It would also be important for making a decision on vaccination strategy, as vaccine is supposed to be the most effective way to confer active and sustained protection. Inactivated vaccines might be associated with worsening of disease and progressive lung damage, yet this overreaction might not be a long-lasting one.
