Contact hypersensitivity (CHS) is a T cell-mediated immune response to epidermal sensitization and subsequent challenge with a hapten. Both sensitization to induce the hapten-specific effector T cells and elicitation to activate expression of their effector function require interactions between the innate and adaptive immune compartments that occur in distinct stages. Application of hapten to the skin induces an inflammatory response that provokes cutaneous dendritic cell activation and CCR7-mediated migration through the efferent lymphatics to the skin-draining lymph nodes where the dendritic cells prime hapten-specific populations of effector T cells (1–5). The skin-derived dendritic cells program Ag-reactive T cells to express receptors such as E-selectin ligand and CCR4 that direct trafficking to the skin (6–9). Hapten challenge of sensitized individuals provokes the trafficking of the primed effector T cells to the skin challenge site and activation to mediate the characteristic edema of the response. Hapten-primed CD8 T cells are the primary effector T cells mediating responses to 2,4-dinitro-1-fluorobenzene (DNFB), oxazolone, and urushiol, the reactive hapten in poison ivy and poison oak (10–13). More recent studies have indicated that separate populations of hapten-specific IFN-γ- and IL-17–producing CD8 T cells are primed in response to DNFB and oxazolone sensitization and that both are required for the elicitation of the response to hapten challenge (14–17).

Hapten challenge of sensitized animals induces the rapid recruitment of the primed CD8 T cells to the challenge site. Within 3 h after challenge, the expression of IL-17 and IFN-γ is detected in the challenge site through localization of the primed CD8 T cells to the vasculature of the skin challenge site and activation by hapten-presenting endothelial cells (16, 17). Although the CD8 T cells are activated within the vasculature of the challenge site to produce IFN-γ and IL-17 within 3 h after challenge, it is important to note that the CD8 T cells do not penetrate the vascular barrier and infiltrate the skin parenchymal tissue at this early time. Both the IL-17 and IFN-γ are required to stimulate endothelial cells and possibly other cells in the challenge site to produce the neutrophil chemoattractants CXCL1 and CXCL2, that direct neutrophils into the parenchymal tissue of the skin challenge site. Neutrophil activation during this early infiltration is required for the subsequent infiltration of the effector CD8 T cells through the endothelial barrier in the challenge site to mediate the CHS response (16, 18). Furthermore, the intensity of this neutrophil activation regulates the numbers of hapten-primed CD8 T cells infiltrating the parenchymal tissue of the challenge site and the magnitude of the edematous response elicited (19).

The inflammatory mediators that are required for localization of the effector CD8 T cells to initiate the innate immune response component of CHS remain poorly defined. IL-1 is rapidly produced by cells in the skin in response to hapten application for sensitization and challenge (20–23). Studies from several investigators using a variety of tools have indicated a requirement for IL-1 in CHS responses. Sensitization of IL-1-deficient mice with trinitrochlorobenzene results in decreased T cell proliferative responses to hapten-labeled stimulator cells and decreased CHS responses to hapten challenge (24, 25). Anti–IL-1 Abs or IL-1 receptor antagonists administered during sensitization also inhibit T cell...
priming for CHS responses and inhibit elicitation of the response when given during challenge of sensitized animals (20, 26, 27). Low CHS responses are also elicited after sensitization and challenge of mice with deficiencies in IL-1 receptor expression or in components of the inflammasome required for IL-1β processing (28–35). Although these studies indicate a requirement for IL-1 receptor signaling at some point during sensitization of hapten-primed T cells and at some point during the recruitment or activation of these T cells to mediate CHS, the points where IL-1 signaling mediates effects that are required for the progression of sensitization and elicitation remain unclear. In this study we used IL-1 receptor-deficient mice to directly examine the requirement for IL-1 receptor signaling for hapten-presenting dendritic cell migration from the sensitized skin to the draining lymph nodes, for the priming of the two effector CD8 T cell populations, and for the recruitment of the hapten-primed effector CD8 T cells to the challenge to elicit the IFN-γ and IL-17 that initiates the elicitation of the response.

Materials and Methods

Mice

C57BL/6 (H-2b) mice were obtained through Dr. Clarence Reeder (National Cancer Institute, Frederick, MD). IL1R−/− mice on the C57BL/6 background (B6.IL1R−/−) were obtained from Jackson Labs (Bar Harbor, ME). Female mice, 8–10 wk of age, were used throughout these studies.

Hapten sensitization and elicitation of CHS

Mice were sensitized to DNFB by painting the shaved abdomen with 25 μl 0.25% DNFB (Sigma Aldrich, St. Louis, MO) in acetone/olive oil (4:1) and 10 μl to each paw on days 0 and +1 (13, 36). On day +5, the ear thickness of hapten-sensitized and control, nonsensitized wild type (WT) C57BL/6 mice were measured using an engineer’s micrometer (Mitutoyo, Tokyo, Japan) and the mice were challenged on each side of each ear with 10 μl DNFB. The increase in ear thickness was measured 24 h later and expressed in micrometers. The ear swelling response is given as the mean increase of each group of four individual animals ± SEM. Mice were sensitized to tetramethylrhodamine isothiocyanate (TRITC) by painting the shaved abdomen with 25 μl 6.67 mg/ml TRITC (Sigma Aldrich, St. Louis, MO) in acetone/dibutylphthalate (1:1) and 10 μl to each paw and to FITC (Sigma Aldrich) by painting the shaved abdomen with 100 μl of a 1% solution in acetone/olive oil (4:1) and 10 μl on each paw.

Abs and cytokines

The following Abs were used for flow cytometry: anti-CD3 mAb, anti-mouse CD11c mAb, anti-CD45 mAb, anti-CD11b mAb, anti-CCR7 mAb (BD Pharmingen, San Diego, CA), F4/80, anti-CD207 mAb, and rat anti-mouse Gr-1 mAb RB6.8C5 i.p. In each experiment using mAb depletion of T cells and was always

Histologic analyses of CHS

Hapten-challenged ears were excised from DNFB-sensitized and nonsensitized WT C57BL/6 and B6.IL1R−/− mice 24 h after challenge with 0.2% DNFB. For staining to detect cellular infiltration into the challenge site, the skin tissue was fixed in 10% formalin and embedded in paraffin, and 8 μm sections were prepared, stained with H&E, and viewed by light microscopy.

Enumeration of hapten-specific T cells producing IFN-γ and IL-17

Frequencies of hapten-specific T cells producing IFN-γ and IL-17 were determined using ELISPOT assays as previously described (16, 37).

ELISPOT plates (Unifilter 350, Polyclonitamins, Rockland, MA) were coated with 4 μg/ml anti–IFN-γ or 2 μg/ml anti–IL-17 mAb and incubated overnight at 4°C. The plates were blocked with 1% BSA in PBS and washed four times with PBS. LNC suspensions from nonsensitized or DNFB-sensitized mice were prepared on day +5 after sensitization, CD8 T cells were enriched by removing the CD4 T cells with anti-CD4 mAb-conjugated magnetic beads (Invitrogen, Carlsbad, CA) and magnetic removal of the cells, and the remaining cells were used as responder cells in the assay. Syngeneic spleen cells from naive mice were treated with 50 μg/ml mitomycin C and then labeled with 100 μg/ml DNBS for use as stimulator cells. Stimulator cells were plated at 5 × 105 cells/well with either 2 × 105, 5 × 105, or 1 x 106 responder cells/well in serum-free HL-1 medium (Bio-Whittaker, Walkersville, MD) supplemented with 1 mM t-glutamine and 1 mM antibiotic. Responder cells plated with unlabeled splenocytes were used as a negative (hapten-specificity) control. After 24 h of culture at 37°C in 5% CO2, cells were removed from the plate by extensive washing with PBS/0.05% Tween-20 (PBS-T). Biotinylated anti–IFN-γ mAb (2 μg/ml) or biotinylated anti–IL-17 mAb (1 μg/ml) was added and the plate was incubated overnight at 4°C. The following day, the plate was washed three times with PBS-T and conjugated streptavidin–alkaline phosphatase was added to each well. After 2 h at room temperature, the plates were washed with PBS-T and NBT/5-bromo-4-choro-30-indolyl substrate (Bio-Rad Laboratories, Hercules, CA) was added to each well. The resulting spots were counted with an ImmunoSpot Series I Analyzer (Cellular Technology, Cleveland, OH) that was designed to detect ELISA spots with predetermined criteria for spot size, shape, and colorimetric density.

Analysis of tissue infiltrating cells by flow cytometry

On day +5, sensitized and naive C57BL/6 and B6.IL1R−/− mice were challenged with DNFB. After 6 or 18 h, the challenged skin was excised and incubated in 0.5% dispase (Invitrogen) at 18°C for 4 h. The next day, the epidermis was separated from the dermis, incubated in 0.5% trypsin (Sigma Aldrich) for 60 min at 37°C, 5% CO2, and pressed through dialysis tubing to isolate individual cells. The cells were washed twice in HBSS, incubated in 0.2% DNase (Roche, Indianapolis, IN) for 10 min at room temperature and washed again. Aliquots of 1 × 107 cells were washed in staining buffer (Dulbecco PBS with 2% FCS/0.2% NaN3) and incubated with 25 μg/ml of each anti-CD4 mAb, GK1.5, and YTS 191. Mice were depleted of CD8 or CD4 T cells or Gr-1+ cells were purchased from BioXCell (West Lebanon, NH). CD8 T cells were depleted by injecting mice with 100 μg of each anti-CD8 mAb, YTS 169, and TIB-150, on three consecutive days before sensitization. CD8 T cells were depleted before sensitization using 100 μg of each anti-CD4 mAb, GK1.5, and YTS 191. Gr-1+ cells that include neutrophils and some monocytes were depleted at the time of hapten challenge of sensitized mice by injecting 150 μg anti–Gr-1 mAb RB6.8C5 i.p. In each experiment using mAb depletion of T cells or Gr-1+ cells, treated sentinel mice were used to evaluate the efficiency of cell depletion by Ab staining and flow cytometry analysis of spleen and lymph node cells (LCNs) or thioglycollate-induced peritoneal exudate cells and was always >95% for CD4 and CD8 T cells and always >85% for Gr-1+ cells when compared with cells from control, rat IgG-treated mice.

Quantitation of CXCL1 production in the skin challenge site by immunobassay

Production of CXCL1 in the skin following hapten application was determined using a CXCL1-specific ELISA. Mice were sensitized with 0.25% DNFB by applying the hapten to the ears (10 μl to both sides of each ear) on days 0 and +1. The shaved trunk skin of both sensitized and nonsensitized mice was challenged with 25 μl DNFB and the challenged skin was removed at 6 or 18 h following challenge, weighed, and homogenized in 500 μl proteinase inhibitor mixture (Sigma Aldrich) with gentle shaking for 30 min. Following centrifugation at 12,000 × g for 10 min the supernatants were collected and the total protein concentration was quantified using a Coomassie Plus Protein Assay Reagent Kit (Pierce, Rockford, IL). All samples were diluted to an equivalent total protein concentration and tested for CXCL1 levels by sandwich ELISA using commercially available anti-CXCL1 mAb to coat and develop the plate and recombinant CXCL1 to generate a standard curve.

Analysis of gene expression by quantitative RT-PCR

RNA was obtained from skin homogenates excised after hapten sensitization or hapten challenge by dissolving the skin in TRIZOL reagent (Invitrogen) with subsequent chloroform extraction. cDNA was synthesized from 2 μg RNA using the TaqMan Reverse Transcription Reagent Kit (Applied Biosystems, Foster City, CA) according to the manufacturer’s instructions. PCR was performed using custom primers and FAM dye-labeled probes (Applied Biosystems, Foster City, CA) for mouse CXCL1, IFN-γ, IL-17, TNF-α, ICAM-1, CCL19, CCL21, and Mip32 (gene assay ID: Mm00433859_m1, Mm00436778_s1, Mm00443358_m1, Mm00430625_s1, Mm00443358_m1, Mm00434165_s1, Mm00436697_s1, and Mm00777741_s1, respectively). The comparative Ct method for relative quantitation of cytokine gene expression was used where log measurements for each sample are made.
during amplification, and the expression level of the Mrlp32 housekeeping gene is subtracted from the expression level for each test cytokine gene. For each test cytokine, the expression level of a single RNA sample prepared from the unchallenged skin of nonsensitized WT mice was used as the calibrator and was arbitrarily set at 1.0, and the expression levels of all other samples were then normalized to the calibrator. Duplicate runs of each individual RNA sample prepared from a single mouse of four mice per group were tested, and the data were expressed as mean test cytokine expression level ± SEM.

Adoptive transfer of CD8 T cells

Groups of C57BL/6 and B6.IL-1R−/− mice were sensitized by application of 25 µl of 6.67 mg/ml TRITC (Sigma Aldrich) to the shaved abdomen and 10 µl to each paw on day 0. On day +1 and on day +2, skin-draining lymph nodes were removed, single-cell suspensions were prepared and washed, and aliquots were stained with combinations of FITC-conjugated anti–I-Ab mAb and allophycocyanin-conjugated anti-CD207 mAb, PerCP- or APC-conjugated anti-CD11c mAb, and PerCP-conjugated anti-CCR7 mAb. The cells were gated on the class II MHC-expressing cells, and the TRITC+/CD11c+/CD207+ cells were analyzed by flow cytometry with sample data collected on 50,000 cells.

Hayten-presenting dendritic cell transfer

C57BL/6 mice were sensitized to 0.25% DNFB on the shaved abdomen and paws, as described previously (36). On day +2, skin-draining lymph nodes were removed and single-cell suspensions were prepared. Cells were incubated with anti-CD11c+ mAb-coated magnetic beads (Miltenyi Biotec, Auburn CA) to isolate purified populations of CD11c+ cells. Aliquots of 3 × 10^5 CD11c+ cells were injected intradermally to naïve C57BL/6 or IL1R−/− mice. On day +4 after transfer, skin-draining lymph nodes from recipient mice as well as sensitized or naïve mice were removed, and single cell suspensions were prepared for use as responders in IFN-γ ELISPOT assays.

Statistical analysis

Statistical analysis to assess differences between experimental groups was performed using Student t test. Differences were considered significant when p < 0.05.

Results

Low magnitude CHS responses elicited in sensitized IL1R−/− mice

To initiate studies investigating the role of IL-1R signaling in the induction and elicitation of CHS, the magnitude of CHS responses to DNFB were compared in WT and IL-1R−/− mice. Groups of WT C57BL/6 and IL1R−/− mice were sensitized with DNFB and then challenged on the ear to elicit the response. When measured 24 h after challenge, the increase in ear thickness of the sensitized IL1R−/− mice was less than half that elicited in sensitized WT mice (Fig. 1A, 1B). Consistent with previous results, CHS responses in sensitized mice depleted of CD8 T cells were nearly decreased to the swelling response observed in the hapten-challenged ears of naive mice (Fig. 1A). In addition, depletion of Gr-1+ cells, which include neutrophils, at the time of hapten challenge of DNFB-sensitized WT and IL-1R−/− mice also decreased the magnitude of the CHS response in both groups of mice (Fig. 1B). DNFB-challenged ears of sensitized and unsensitized WT C57BL/6 and B6.IL-1R−/− mice were excised 24 h after hapten challenge and prepared sections were stained with H&E. Challenged ears excised from sensitized WT mice exhibited the characteristic leukocytic infiltration accompanied by tissue edema and these characteristics were absent in challenged ears from sensitized B6.IL-1R−/− mice as well as in hapten-challenged ears from naive control WT C57BL/6 and B6.IL-1R−/− mice (Fig. 1C).

Previous studies have demonstrated that prior CXCL1-mediated neutrophil infiltration into the skin challenge site at 6 h after challenge is required to induce subsequent T cell infiltration (16, 18). To determine whether the lower CHS response elicited in sensitized IL1R−/− mice was associated with decreased infiltration of neutrophils into the skin challenge site, challenged skin was excised at 6 h after challenge and digested, and cell suspensions were prepared and stained with Abs to identify infiltrating neutrophils and macrophages. The infiltration of Gr-1+ cells that include neutrophils was markedly decreased into the challenge site of sensitized IL1R−/− mice when compared with the challenge site of sensitized WT mice (Fig. 2). In contrast, little to no difference was observed with the presence of CD11b+ cells that include monocytes and F4/80+ monocytes and macrophages in the skin challenge site of sensitized WT C57BL/6 and B6.IL-1R−/− mice. As observed previously (16, 17), T (CD3+) cell infiltration into the challenge site was not observed at 6 h after challenge of sensitized mice (data not shown).

The infiltration of different leukocyte populations into the skin challenge site of sensitized WT C57BL/6 and B6.IL-1R−/− mice 18 h after challenge was also assessed. In the hapten challenge site of sensitized WT animals, infiltrating Gr-1+ cells that include neutrophils and CD3+ cells (i.e., T cells) into the skin challenge site were clearly present, whereas infiltration of these leukocyte populations into the challenge site of sensitized IL1R−/− mice was markedly decreased (Fig. 3). Interestingly, the presence of F4/80+ cells (macrophages) was decreased in the challenge site of the WT and IL-1R−/− mice at this time when compared with 6 h after challenge.

Decreased production of CXCL1 induced in the challenge site of IL-1R−/− mice during the elicitation of CHS

To investigate potential mechanisms underlying the low neutrophil infiltration into the skin challenge site of sensitized IL1R−/− mice, the production of the neutrophil chemoattractant CXCL1 in the site was tested. Hapten-challenged skin was excised from groups of sensitized WT and IL-1R−/− mice 6 and 18 h after challenge, and prepared tissue protein was tested for quantity of CXCL1 by ELISA. CXCL1 production was decreased in the skin challenge site of sensitized IL1R−/− mice more than 70% to that induced in the challenge site of sensitized WT mice at both time points (Fig. 4).

Because the production of CXCL1 within the site at 6 h after challenge is dependent on the hapten-mediated activation of hapten primed CD8 T cell populations producing IFN-γ and IL-17, the expression of these cytokines in the challenge site at this time point was tested. Whole-cell RNA was prepared from challenge skin homogenates of sensitized WT and IL-1R−/− mice and unsensitized WT mice and tested for expression levels of IFN-γ and IL-17, as well as TNF-α and ICAM-1, which are required for the localization of the CD8 T cells to the hapten challenge site (17). Expression levels of IFN-γ and IL-17 were significantly decreased in challenged skin of sensitized IL-1R−/− mice when compared with WT mice (Fig. 5). Furthermore, expression levels of TNF-α and ICAM-1 in the challenged skin of IL-1R−/− mice were near levels expressed in the skin after hapten challenge of naive WT mice.

IL-1 signaling is required to induce hapten-primed CD8 T cells to activate endothelial cells in the skin challenge site to produce CXCL1

Because there was suboptimal expression of cytokines associated with the CD8 T cell mediated response after hapten challenge of...
DNFB-sensitized IL-1R$^{-/-}$ mice, the ability of hapten-primed CD8 T cells to function in the IL-1R–deficient environment was investigated. First, aliquots of hapten-primed CD8 T cells from the lymph nodes of sensitized WT C57BL/6 mice were transferred to naive WT or B6.IL-1R$^{-/-}$ mice and the recipients as well as a group of nonrecipient WT mice were challenged on the ears with DNFB and the increase in ear thickness was determined 24 h later.

**FIGURE 1.** Decreased CHS responses elicited in hapten-sensitized IL-1R$^{-/-}$ mice. A, Groups of WT C57BL/6 and B6.IL-1R$^{-/-}$ mice were sensitized with 0.25% DNFB on days 0 and +1. The indicated groups of mice were treated with anti-CD8 mAbs on three consecutive days prior to sensitization. On day +5 following sensitization, sensitized and nonsensitized (naive) mice were challenged on the ears with 0.2% DNFB and the increase in ear thickness was measured 24 h later. *$p < 0.02$. B, Groups of IL-1R$^{-/-}$ and WT C57BL/6 mice were sensitized with 0.25% DNFB on days 0 and +1. On day +5 following sensitization, sensitized and nonsensitized (naive) WT C57BL/6 mice were challenged on the ears with 0.2% DNFB and the increase in ear thickness was measured 24 h later. The indicated groups of sensitized mice were treated with a single dose of anti-Gr-1 mAb at the time of hapten challenge. The mean increase in ear thickness ± SEM for four individual mice per group is shown. *$p < 0.045$. Results are representative of two individual experiments. C, Ears from DNFB-sensitized and unsensitized WT C57BL/6 and B6.IL-1R$^{-/-}$ mice were challenged with 0.2% DNFB and 24 h later the ears were excised and fixed in formalin, and prepared sections were stained with H&E and representative images were captured by light microscopy. Original magnification ×200.

**FIGURE 2.** Decreased cellular infiltration in skin challenge site of DNFB-sensitized and -challenged IL-1R$^{-/-}$ mice at 6 h postchallenge. WT C57BL/6 and B6.IL-1R$^{-/-}$ mice were sensitized with DNFB on days 0 and +1 and challenged with 0.2% DNFB. Challenged skin was excised 6 h later, digested to prepare single cell suspensions of the tissue, and cell aliquots were stained with fluorescent Abs to identify infiltrating neutrophils, monocytes, and macrophages. Representative samples from four to five different animals analyzed are shown. Results are representative of two individual experiments.
challenge in WT recipients, whereas the response in IL-1R$^{-/-}$ recipients was significantly lower and similar to the increase in ear swelling observed following challenge of naive WT mice (Fig. 6A).

The early CXCL1 required for the progression of the CHS response is produced primarily by endothelial cells in the challenge site that are stimulated by effector CD8 T cell-produced IFN-γ and IL-17 (17). Because early CXCL1 was not induced during challenge of sensitized IL-1R$^{-/-}$ mice, the ability of CD8 T cells from sensitized WT mice to restore early CXCL1 production in the skin challenge site of IL-1R$^{-/-}$ mice was tested. WT C57BL/6 and B6.IL-1R$^{-/-}$ mice were sensitized with DNFB, and 4 d later purified CD8$^+$ T cells were prepared from the skin-draining lymph nodes and transferred to naive WT or IL1R$^{-/-}$ recipients. The recipients were then challenged and the challenged skin was excised 6 h later to prepare tissue-free homogenates and test CXCL1 production by ELISA. Whereas hapten-primed CD8 T cells from sensitized WT donors induced high levels of CXCL1 production in the challenged skin of naive IL1R$^{-/-}$ recipients, these CD8 T cells failed to induce CXCL1 in the challenged skin of naive WT recipients, these CD8 T cells failed to induce the expression of CXCL1 in the skin challenge site of the naive IL-1R$^{-/-}$ recipients, and this was associated with induced expression levels of IL-17 and IFN-γ that were equivalent to those observed in the hapten-challenged skin of naive WT mice (Fig. 6C). These results indicate that the transferred WT effector CD8 T cells are not being activated within the challenge site of the IL-1R$^{-/-}$ recipients; this accounts for the low production of CXCL1 induced in response to hapten challenge in the site and, in part, accounts for the inability to passively transfer CHS responses to the naive IL-1R$^{-/-}$ mice.

**T cell priming is deficient in sensitized IL1R$^{-/-}$ mice**

Because T cell activities inducing inflammatory events in the hapten challenge site of sensitized IL1R$^{-/-}$ mice were compromised, the magnitude of CD8 T cell priming in response to hapten sensitization was compared in IL1R$^{-/-}$ and WT mice. To test this, CD8 T cell-enriched cell suspensions were prepared from skin-draining lymph nodes of DNFB-sensitized WT and IL1R$^{-/-}$ mice, aliquots were cultured with hapten-labeled syngeneic splenocytes, and the numbers of hapten-specific CD8 T cells producing either IFN-γ or IL-17 were determined by ELISPOT analysis (Fig. 7). As previously observed in hapten-sensitized WT C57BL/6 mice (16), numbers of hapten-specific CD8$^+$ T cells producing IFN-γ were ~5-fold higher than numbers of hapten-specific CD8$^+$ T cells producing IL-17. The numbers of hapten-specific CD8$^+$ T cells from sensitized IL1R$^{-/-}$ mice producing either IFN-γ or IL-17 were decreased by >65% compared with those induced in the sensitized WT mice.

**IL-1 receptor signaling is required for migration of hapten-presenting dendritic cells into the skin-draining lymph nodes**

The migration of hapten-presenting dendritic cells from the sensitized skin into the skin-draining lymph nodes of IL-1R$^{-/-}$ mice was investigated as an underlying mechanism for the low hapten-specific CD8 T cell priming induced in response to DNFB sensitization. Groups of WT C57BL/6 and B6.IL1R$^{-/-}$ mice were sensitized with the fluorescent hapten TRITC, and the skin-draining lymph nodes were removed 24 and 48 h after hapten application. Single-cell suspensions were prepared and stained with anti-class II MHC, anti-CD11c mAb, anti-CD207, and anti-CCR7 mAb to determine the presence of hapten-labeled skin-

**FIGURE 3.** Decreased cellular infiltration in skin challenge site of DNFB-sensitized and -challenged IL-1R$^{-/-}$ mice at 18 h postchallenge. WT C57BL/6 and B6.IL-1R$^{-/-}$ mice were sensitized with DNFB on days 0 and +1 and challenged with 0.2% DNFB. Challenged skin was excised 18 h later, digested to prepare single cell suspensions of the tissue, and cell aliquots were stained with fluorescent anti-CD11b and anti-Gr-1 Abs to identify infiltrating neutrophils and monocytes, with fluorescent anti-F4/80 Ab to identify macrophages, and with fluorescent anti-CD3 mAb to detect infiltrating T cells. Representative samples from four to five different animals analyzed are shown. Results are representative of two individual experiments.

**FIGURE 4.** Decreased early CXCL1 production in the skin challenge site of sensitized IL-1R$^{-/-}$ mice. WT C57BL/6 and B6.IL-1R$^{-/-}$ mice were sensitized and challenged with DNFB. Challenged skin from each mouse was removed 6 or 18 h after hapten challenge, weighed, and homogenized. Tissue-free supernatants were tested by ELISA to determine amounts of CXCL1. The mean concentration of CXCL1 ± SEM for four individual mice/group is shown. Results are representative of two individual experiments of four individual mice in each. *p = 0.04.
derived and lymph node resident dendritic cells by flow cytometry. Small numbers of lymph node class II MHC+/CD11c+ cells from naive mice expressing TRITC were considered background, and many of the class II MHC+/CD11c+ cells from naive mice expressed CCR7 and not CD207 indicating that they were resident dendritic cells (Fig. 8A). The majority of the class II MHC+/CD11c+ cells in the skin-draining lymph nodes of sensitized WT mice expressed TRITC as well as CD207, indicating emigration from the skin. In contrast, there was a marked decrease in class II MHC+/CD11c+ cells in the skin-draining lymph nodes of sensitized IL-1R<sup>−/−</sup> mice. However, many of the class II MHC+/CD11c+ cells in TRITC-sensitized IL-1R<sup>−/−</sup> mice did express

**FIGURE 5.** Decreased expression of early inflammatory mediators in response to challenge of sensitized IL-1R<sup>−/−</sup> mice. Groups of WT C57BL/6 and B6.IL-1R<sup>−/−</sup> mice were sensitized and challenged with DNFB. Challenged areas of skin and skin from naive nonchallenged mice were excised 6 h after challenge, snap frozen, and homogenized. Whole-cell RNA was prepared and was used to assess mRNA expression of TNF-α, IL-17, IFN-γ, and ICAM-1 in the skin samples by quantitative RT-PCR. The mean expression level for each of four samples per group ± SEM is shown. The results are representative of two individual experiments. *p ≤ 0.05.

**FIGURE 6.** Deficient activation of transferred immune WT T cells in IL-1R<sup>−/−</sup> mice. WT C57BL/6 and B6.IL-1R<sup>−/−</sup> mice were depleted of CD4 T cells and then sensitized with 0.25% DNFB on days 0 and +1. On day +4, cell suspensions were prepared from skin-draining lymph nodes and 4 × 10<sup>6</sup> T cell aliquots were transferred i.v. to naive WT or naive IL-1R<sup>−/−</sup> mice that were then immediately challenged with 0.2% DNFB on the ears to determine passive transfer of the CHS response or on a shaved area of trunk skin to determine activation of the transferred T cells within the challenge site. A, The increase in ear thickness was measured 24 h later in ear-challenged groups of four recipient mice or challenged nonrecipient WT C57BL/6 mice. The mean increase in ear thickness ± SEM for four individual mice per group is shown. *p ≤ 0.002. B, Groups of sensitized recipient mice and nonrecipient WT C57BL/6 mice were challenged with 0.2% DNFB on a shaved area of trunk skin and the challenged skin was removed 6 h later, weighed, and snap frozen. Frozen skin was homogenized and whole-cell RNA was prepared and used to assess mRNA expression of CXCL1, IL-17, and IFN-γ in the skin samples by quantitative RT-PCR. The mean expression level for each of four samples per group ± SEM is shown. *p ≤ 0.05. All results are representative of two individual experiments.
later, recipient skin-draining lymph nodes were taken, and the CD8 T cells were cultured with 5A sensitized WT mice (Fig. 9 of the dendritic cells potently induced hapten-specific CD8 T cells T cells producing IFN- from the recipient mice and numbers of hapten-specific CD8 days after the transfer, skin-draining lymph nodes were removed prepared from lymph nodes of FITC-sensitized WT mice and sitized with DNFB on days 0 and +1, and on day +2 CD11c+ cells flow cytometry (Fig. 9 anti-CD4 mAb conjugated to magnetic beads. Aliquots of 2 × 10^5 DNBS-labeled or unlabeled specific splenocytes on anti–IFN-γ or anti–IL-17 mAb-coated ELISPOT plates. After 24 h, cells were removed and the ELISPOT assay was developed to detect numbers of IFN-γ− or IL-17−producing cells. The mean number ± SEM of cytokine-producing T cells per 2 × 10^5 cells in triplicate cultures for three mice is shown after subtraction of spots from control wells containing the T cells with unlabeled stimulator cells (>5 spots per well). Results are representative of two individual experiments. p < 0.02.

TRITC as well as CCR7 but not CD207, indicating the acquisition of hapten by lymph node resident dendritic cells after sensitization of IL-1R^−/− mice. Quantification of the flow cytometry results indicated significant decreases in the number of hapten-presenting dendritic cells in the skin-draining lymph nodes of TRITC-sensitized IL-1R^−/− mice compared with sensitized WT mice at both 24 and 48 h after TRITC application to the skin (Fig. 8B).

We next asked whether the deficiency in hapten-presenting dendritic cell migration into the skin-draining lymph nodes in IL-1R^−/− mice could be overcome and whether T cell priming could be restored by transfer of hapten-expressing dendritic cells from sensitized WT mice to IL1R^−/− mice. WT mice were sensitized with DNFB on days 0 and +1, and on day +2 CD11c+ cells were purified from skin-draining lymph nodes and transferred intradermally into groups of WT or IL-1R^−/− naive mice. Five days after the transfer, skin-draining lymph nodes were removed from the recipient mice and numbers of hapten-specific CD8 T cells producing IFN-γ were tested by ELISPOT assay. Transfer of the dendritic cells potently induced hapten-specific CD8 T cells producing IFN-γ in WT recipients, although the numbers were lower than the numbers observed in lymph nodes of directly sensitized WT mice (Fig. 9A). Hapten-specific T cells producing IFN-γ were decreased by more than 75% in IL1R^−/− recipients of the dendritic cells from sensitized WT donors.

Because transfer of WT hapten-presenting dendritic cells to IL-1R^−/− mice resulted in poor priming of hapten-specific CD8 T cells, the trafficking of transferred WT hapten-presenting dendritic cells to the skin-draining lymph nodes in the absence of recipient IL-1 receptor signaling was assessed. CD11c+ cells were prepared from lymph nodes of FITC-sensitized WT mice and transferred intradermally to naive WT or IL1R^−/− mice. Two days later, recipient skin-draining lymph nodes were taken, and the presence of the transferred FITC+CD11c+ cells was assessed by flow cytometry (Fig. 9B). Whereas the transferred FITC+CD11c+ cells were clearly present in the skin-draining lymph nodes of WT recipients, in the skin-draining lymph nodes of the IL1R^−/− recipients these cells were near the background levels of the nonrecipient WT mice, suggesting defective trafficking of the transferred WT dendritic cells to the lymph nodes of the IL-1R-deficient mice.

Previous studies from this laboratory have demonstrated the requirement for CCR7 binding chemokines for hapten-presenting dendritic cell trafficking from the sensitized skin to the skin-draining lymph nodes (1). When the mRNA expression levels of CCL19 and CCL21 were compared in the unchallenged and hapten-challenged skin of WT and IL-1R^−/− mice, the levels in unchallenged skin was similar in both groups of mice, but there was a significant decrease in the expression of CCL21 in the skin of IL-1R^−/− mice induced by hapten application (Fig. 10).

Discussion

Hapten application to sensitize and elicit CHS responses initiates an intricate series of inflammatory events that result in hapten-specific effector CD8 T cell priming and culminate in the migration and activation of the T cells in the skin challenge site to mediate the characteristic edema of the response. Studies from this and other laboratories have shown that hapten application to the skin rapidly induces the production of the acute phase cytokines IL-1α, IL-1β, and TNF-α (17, 20–22). Early localization of hapten-primed CD8 T cells to the challenge site requires the TNF-α-induced expression of ICAM-1 resulting in their activation to produce IL-17 and IFN-γ that, in turn, stimulates endothelial cells within the challenge site to produce the neutrophil chemo-attractants CXCL1 and CXCL2 as early as 3 h after challenge (17). Consistent with the requirement for neutrophil infiltration and activation for the subsequent infiltration of the CD8 T cells into the challenge site, antagonism of this chemokine production inhibits neutrophil and subsequent CD8 T cell infiltration into the site as well as the CHS response. The mechanisms directing localization of the effector CD8 T cells to the challenge site and the infiltration of neutrophils into the skin challenge site remain unclear. The initial goal of this study was to test the role of IL-1 signaling in the early events that lead to hapten-primed CD8 T cell localization and activation to induce CXCL1 production in the challenged skin of sensitized mice.

Although both hapten sensitization and challenge to elicit CHS responses to various haptons are clearly inhibited by neutralization or the absence of IL-1 (20, 24–29, 32, 33), the points during the sensitization and elicitation phases of the response where IL-1R signaling is required have not been clearly identified. The initial results of this study confirm those of previous studies, indicating absent or decreased CHS responses when mice are sensitized and challenged in the absence of IL-1R signaling (26, 30). In trinitrochlorobenzene-sensitized mice with a targeted deletion in the IL-1α or both IL-1α and IL-1β gene, T cell proliferative responses during culture with hapten-labeled stimulator cells are markedly decreased, suggesting decreased hapten-specific T cell priming in sensitized IL-1^−/− mice (24, 25). In the current study, we have shown the decreased priming of the hapten-specific CD8 T cell populations producing IL-17 and IFN-γ that are the effector T cells required for elicitation of the response. Recent studies from Chung et al. (38) have indicated that IL-1R signaling to Ag-specific CD4 T cells is required for their development to IL-17 producing cells. Hapten-specific CD8 T cell development to IL-17-producing cells was virtually absent after sensitization of IL-1R^−/− mice, whereas CD8 T cells producing IFN-γ were reduced more than 60% of that observed in sensitized WT mice, but the presence of these T cells was observed at low numbers. This defective CD8 T cell priming could be due to decreases in hapten presentation in the lymph nodes or a requirement for IL-1-mediated signaling by CD8 T cells developing to IL-17–producing cells. Although both are likely to contribute to this deficiency, the presence of low-level hapten-specific CD8 T cells producing IFN-γ suggests that the absence of IL-17–producing CD8 T cells is consistent with their need for IL-1R signaling during development.
This defective effector CD8 T cell priming led us to test whether hapten-presenting dendritic cell populations were trafficking from the skin sensitization site to the skin-draining lymph nodes. Although several investigators have shown a decreased percentage of hapten-expressing Langerhans cells in the lymph nodes when the IL-1 signaling pathway was absent or antagonized during hapten sensitization (20, 24, 27), it has remained unclear whether this decrease was due to inhibition of dendritic cell activation within the sensitized skin or due to the inhibited migration of the dendritic cells from the sensitized skin to the draining lymph nodes. In WT mice, the activation of dendritic cell populations in the epidermis and dermis during inflammatory events induced by hapten application results in dendritic cell acquisition of hapten, the downregulation of molecules tethering the cells within the skin, and the upregulation of molecules (e.g., CCR7) that direct their migration into the efferent lymphatics and then into the T cell-rich areas of the draining lymph nodes (39, 40). After sensitization of IL-1R\(^\text{−/−}\) mice, there was a marked decrease in the presence of hapten-presenting dendritic cells in the lymph nodes. There is no marked difference in the number of CD11c\(^+\)/class II MHC\(^+\) cells in the epidermis or in the spleen (D.D. Kish, data not shown). This finding suggests that the defect lies in the ability of the skin-derived dendritic cells to traffic to the lymph nodes. In support of this, when hapten-presenting dendritic cells isolated from the draining lymph nodes of hapten-sensitized WT mice were injected intradermally into naive WT versus IL-1R\(^\text{−/−}\) mice, the injected dendritic cells trafficked to the lymph nodes of WT recipients and primed hapten-specific CD8 T cells much more efficiently than the dendritic cells injected into IL-1R\(^\text{−/−}\) recipients. Consistent with this result, the expression of the CCR7 ligand CCL21 was expressed at significantly lower levels in hapten-sensitized skin of IL-1R\(^\text{−/−}\) mice versus WT mice. It is important to note that mRNA expression levels of the other CCR7 ligand, CCL19, were similar in the two groups of mice. These results clearly demonstrate a defect in this hapten-presenting dendritic cell migration following sensitization that is likely to contribute to the decreased effector CD8 T cell priming observed in the sensitized IL-1R\(^\text{−/−}\) mice.

Our previous results have indicated that administration of anti-CCL19 mAb at the time of hapten sensitization inhibits hapten-presenting dendritic cell trafficking from the skin to the lymph nodes and CHS responses to subsequent hapten challenge (1). However, the level of hapten-specific CD8 T cell priming in this previous study was not altered by the anti-CCL19 Ab treatment. Because hapten also drains through the efferent lymphatics into the lymph node and is picked up by lymph node resident dendritic cells and other Ag presenting cells (41), we had postulated that the low numbers of hapten-reactive CD8 T cells primed were through...
this mechanism. The results of the current study indicate that all the CD11c+ dendritic cells in the lymph nodes of sensitized IL-1R$^{-/-}$ mice have acquired the hapten through this process rather than through the trafficking of dendritic cells from the sensitized skin to the lymph nodes.

In addition to the decreases in hapten-specific CD8 T cell priming in IL-1R$^{-/-}$ mice, two points indicate that it is more than a decrease in the number of effector CD8 T cells underlying the absence of a CHS response. First is the low induction of CXCL1 within the challenge site 6 h after challenge of sensitized IL-1R$^{-/-}$ mice as well as the nearly absent neutrophil infiltration into the site at this time. Second is the inability of transferred hapten-primed CD8 T cells from WT donors to correct these defects following challenge of naive IL-1R$^{-/-}$ mice. After 24 h, skin-draining lymph nodes were removed from recipient mice as well as from naive WT mice and aliquots of prepared single cell suspensions were stained with PE-conjugated anti-CD11c mAb and the presence of the transferred FITC+/CD11c+ cells assessed by flow cytometry. Percentages in the upper right-hand quadrants indicate the percentage of CD11c+ cells expressing FITC. Results are representative of two different experiments.

Collectively, the results of the current studies extend studies indicating the absence of CHS responses in the absence of IL-1R signaling. The current study has identified the need for IL-1R signaling for the directed migration of skin-derived dendritic cells to lymph nodes in IL-1R$^{-/-}$ mice.

**FIGURE 9.** Deficient migration of hapten-presenting WT dendritic cells to lymph nodes in IL-1R$^{-/-}$ mice. A, C57BL/6 mice were sensitized with 0.25% DNFB on days 0 and +1. On day +2, skin-draining lymph nodes were removed and single cell suspensions prepared. Purified populations of CD11c+ cells were prepared using anti-CD11c mAb-coated magnetic beads. Aliquots of $3 \times 10^5$ CD11c+ cells were injected intradermally to naive WT C57BL/6 and B6. IL-1R$^{-/-}$ mice. On day +4 after the transfer, skin-draining lymph nodes were removed from recipient mice as well as from DNFB-sensitized and naive WT mice and tested for numbers of hapten-specific CD8 T cells producing IFN-γ by ELISPOT assay. *p < 0.01. B, WT C57BL/6 mice were sensitized with 1% FITC on day 0. On day +2, skin-draining lymph nodes were removed, single cell suspensions were prepared, and purified populations of CD11c+ cells were prepared using anti-CD11c mAb-coated magnetic beads. Aliquots of $3 \times 10^5$ CD11c+ cells were injected intradermally into naive wild type or IL-1R$^{-/-}$ mice. After 24 h, skin-draining lymph nodes were removed from recipient mice as well as from naive WT mice and aliquots of prepared single cell suspensions were stained with PE-conjugated anti-CD11c mAb and the presence of the transferred FITC+/CD11c+ cells assessed by flow cytometry.

**FIGURE 10.** Decreased induction of CCL21 expression in the sensitized skin of IL-1R$^{-/-}$ mice. Groups of WT C57BL/6 and B6.IL-1R$^{-/-}$ mice were sensitized with 0.25% DNFB on days 0 and +1. Skin was excised from sensitized mice and naive C57BL/6 and IL1R$^{-/-}$ mice 3 h after the second application of hapten. Skin was homogenized and whole-cell RNA was prepared and used to assess mRNA expression of CCL19 and CCL21 in the skin samples by quantitative RT-PCR. The mean expression level for each of four samples per group ± SEM is shown. *p < 0.04.
cells to the draining lymph nodes to prime T cells and defects in the localization of hapten-primed effector T cell populations within the challenge site. Each of these events is essential for optimal elicitation of CHS responses and accounts for the minimal responses observed following hapten sensitization and challenge of the IL-IR-/- mice. In light of recent clinical reports that treatment with IL-1R antagonist is efficacious in reducing inflammation and improving islet β-cell function in patients with type 2 diabetes mellitus and in reducing skin inflammation and arthritis in psoriatic patients (43–45), this strategy would be expected to have efficacy in decreasing inflammation during ongoing allergic contact dermatitis responses.
